Abstract

Accurate assessment of anthropogenic carbon dioxide (CO_2) emissions and their redistribution among the atmosphere, ocean, and terrestrial biosphere is important to better understand the global carbon cycle, support the development of climate policies, and project future climate change. Here we describe datasets and a methodology to quantify all major components of the global carbon budget, including their uncertainties, based on the combination of a range of data, algorithms, statistics and model estimates and their interpretation by a broad scientific community. We discuss changes compared to previous estimates, consistency within and among components, alongside methodology and data limitations. CO_2 emissions from fossil fuel combustion and cement production (E_{FF}) are based on energy statistics and cement production data, respectively, while emissions from Land-Use Change (E_{LUC}), mainly deforestation, are based on combined evidence from land-cover change data, fire activity associated with deforestation, and models. The global atmospheric CO_2 concentration is measured directly and its rate of growth (G_{ATM}) is computed from the annual changes in concentration. The mean ocean CO_2 sink (S_{OCEAN}) is based on observations from the 1990s, while the annual anomalies and trends are estimated with ocean models. The variability in S_{OCEAN} is evaluated with data products based on surveys of ocean CO_2 measurements. The global residual terrestrial CO_2 sink (S_{LAND}) is estimated by the difference of the other terms of the global carbon budget and compared to results of independent Dynamic Global Vegetation Models forced by observed climate, CO_2 and land cover change (some including nitrogen-carbon interactions). *We compare the variability and mean land and ocean fluxes to estimates from three atmospheric inverse methods for three broad latitude bands.* All uncertainties are reported as $\pm 1\sigma$, reflecting the current capacity to characterise the annual estimates of each component of the global carbon budget. For the last decade available (2004–2013), E_{FF} was $8.9 \pm 0.4 \text{ GtC yr}^{-1}$, E_{LUC} $0.9 \pm 0.5 \text{ GtC yr}^{-1}$, G_{ATM} $4.3 \pm 0.1 \text{ GtC yr}^{-1}$, S_{OCEAN} $2.6 \pm 0.5 \text{ GtC yr}^{-1}$, and S_{LAND} $2.9 \pm 0.8 \text{ GtC yr}^{-1}$. For year

Interactive Discussion

2013 alone, E_{FF} grew to $9.9 \pm 0.5 \text{ GtC yr}^{-1}$, 2.3% above 2012, continuing the growth trend in these emissions, E_{LUC} was $0.9 \pm 0.5 \text{ GtC yr}^{-1}$, G_{ATM} was $5.4 \pm 0.2 \text{ GtC yr}^{-1}$, S_{OCEAN} was $2.9 \pm 0.5 \text{ GtC yr}^{-1}$ and S_{LAND} was $2.5 \pm 0.9 \text{ GtC yr}^{-1}$. G_{ATM} was high in 2013 reflecting a steady increase in E_{FF} and smaller and opposite changes between S_{OCEAN} and S_{LAND} compared to the past decade (2004–2013). The global atmospheric CO_2 concentration reached $395.31 \pm 0.10 \text{ ppm}$ averaged over 2013. We estimate that E_{FF} will increase by 2.5% (1.3–3.5%) to $10.1 \pm 0.5 \text{ GtC}$ in 2014 ($37.0 \pm 1.9 \text{ GtCO}_2 \text{ yr}^{-1}$), 65% above emissions in 1990, based on projections of World Gross Domestic Product and recent changes in the carbon intensity of the economy. With this projection, cumulative emissions of CO_2 will reach about $545 \pm 55 \text{ GtC}$ ($2000 \pm 200 \text{ GtCO}_2$) for 1870–2014, about 75% from E_{FF} and 25% from E_{LUC} . This paper documents changes in the methods and datasets used in this new carbon budget compared with previous publications of this living dataset (Le Quéré et al., 2013, 2014). All observations presented here can be downloaded from the Carbon Dioxide Information Analysis Center (doi:10.3334/CDIAC/GCP_2014).

Italic font highlights significant methodological changes and results compared to the 2013 manuscript that accompanies this living data.

1 Introduction

The concentration of carbon dioxide (CO_2) in the atmosphere has increased from approximately 277 parts per million (ppm) in 1750 (Joos and Spahni, 2008), the beginning of the Industrial Era, to 395.31 in 2013 (Dlugokencky and Tans, 2014). Daily averages went above 400 ppm for the first time at Mauna Loa station in May 2013 (Scripps, 2013). This station holds the longest running record of direct measurements of atmospheric CO_2 concentration (Tans and Keeling, 2014; Fig. 1). The atmospheric CO_2 increase above preindustrial levels was initially, primarily, caused by the release of carbon to

the atmosphere from deforestation and other land-use change activities (Ciais et al., 2013). While emissions from fossil fuel combustion started before the Industrial Era, they only became the dominant source of anthropogenic emissions to the atmosphere from around 1920 and their relative share continued to increase until present. Anthropogenic emissions occur on top of an active natural carbon cycle that circulates carbon between the atmosphere, ocean, and terrestrial biosphere reservoirs on time scales from days to millennia, while exchanges with geologic reservoirs have even longer timescales (Archer et al., 2009).

The global carbon budget presented here refers to the mean, variations, and trends in the perturbation of CO₂ in the atmosphere, referenced to the beginning of the Industrial Era. It quantifies the input of CO₂ to the atmosphere by emissions from human activities, the growth of CO₂ in the atmosphere, and the resulting changes in the storage of carbon in the land and ocean reservoirs in response to increasing atmospheric CO₂ levels, climate change and variability, and other anthropogenic and natural changes (Fig. 2). An understanding of this perturbation budget over time and the underlying variability and trends of the natural carbon cycle are necessary to understand the response of natural sinks to changes in climate, CO₂ and land use change drivers, and the permissible emissions for a given climate stabilization target.

The components of the CO₂ budget that are reported in this paper include separate estimates for (1) the CO₂ emissions from fossil fuel combustion and cement production (E_{FF}), (2) the CO₂ emissions resulting from deliberate human activities on land leading to Land-Use Change (LUC; E_{LUC}), (3) the growth rate of CO₂ in the atmosphere (G_{ATM}), and the uptake of CO₂ by the “CO₂ sinks” in (4) the ocean (S_{OCEAN}) and (5) on land (S_{LAND}). The CO₂ sinks as defined here include the response of the land and ocean to elevated CO₂ and changes in climate and other environmental conditions. The global emissions and their partitioning among the atmosphere, ocean and land are in balance:

$$E_{FF} + E_{LUC} = G_{ATM} + S_{OCEAN} + S_{LAND} \quad (1)$$

Interactive Discussion

G_{ATM} is usually reported in ppm yr^{-1} , which we convert to units of carbon mass using $1 \text{ ppm} = 2.120 \text{ GtC}$ (Prather et al., 2012; Table 1). We also include a quantification of E_{FF} by country, computed with both territorial and consumption based accounting (see methods).

Equation (1) partly omits two kinds of processes. The first is the net input of CO_2 to the atmosphere from the chemical oxidation of reactive carbon-containing gases from sources other than fossil fuels (e.g. fugitive anthropogenic CH_4 emissions, industrial processes, and changes of biogenic emissions from changes in vegetation, fires, wetlands, etc.), primarily methane (CH_4), carbon monoxide (CO), and volatile organic compounds such as isoprene and terpene. The second is the anthropogenic perturbation to carbon cycling in terrestrial freshwaters, estuaries, and coastal areas, that modifies lateral fluxes from land ecosystems to the open ocean, the evasion CO_2 flux from rivers, lakes and estuaries to the atmosphere, and the net air-sea anthropogenic CO_2 flux of coastal areas (Regnier et al., 2013). These flows are omitted in absence of annual information on the natural versus anthropogenic perturbation terms of these loops of the carbon cycle, and they are discussed in Sect. 2.7. The inclusion of these fluxes of anthropogenic CO_2 would affect the estimates of, and partitioning between, S_{LAND} and S_{OCEAN} in Eq. (1) in complementary ways, but would not affect the other terms in Eq. (1).

The CO_2 budget has been assessed by the Intergovernmental Panel on Climate Change (IPCC) in all assessment reports (Ciais et al., 2013; Denman et al., 2007; Prentice et al., 2001; Schimel et al., 1995; Watson et al., 1990), and by others (e.g. Ballantyne et al., 2012). These assessments included budget estimates for the decades of the 1980s, 1990s (Denman et al., 2007) and, most recently, the period 2002–2011 (Ciais et al., 2013). The IPCC methodology has been adapted and used by the Global Carbon Project (GCP, www.globalcarbonproject.org), who has coordinated a cooperative community effort for the annual publication of global carbon budgets up to year 2005 (Raupach et al., 2007; including fossil emissions only), year 2006 (Canadell et al., 2007), year 2007 (published online; GCP, 2007), year 2008 (Le Quéré et al., 2009),

[Title Page](#)[Abstract](#)[Instruments](#)[Data Provenance & Structure](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

year 2009 (Friedlingstein et al., 2010), year 2010 (Peters et al., 2012b), year 2012 (Le Quéré et al., 2013; Peters et al., 2013) and most recently, year 2013 (Le Quéré et al., 2014). Where the carbon budget year refers to the initial year of publication. Each of these papers updated previous estimates with the latest available information for the entire time series. From 2008, these publications projected fossil fuel emissions for one additional year using the projected World Gross Domestic Product and estimated improvements in the carbon intensity of the economy.

We adopt a range of ± 1 standard deviation (σ) to report the uncertainties in our estimates, representing a likelihood of 68 % that the true value will be within the provided range if the errors have a Gaussian distribution. This choice reflects the difficulty of characterising the uncertainty in the CO₂ fluxes between the atmosphere and the ocean and land reservoirs individually, particularly on an annual basis, as well as the difficulty of updating the CO₂ emissions from LUC. A likelihood of 68 % provides an indication of our current capability to quantify each term and its uncertainty given the available information. For comparison, the Fifth Assessment Report of the IPCC (AR5) generally reported a likelihood of 90 % for large datasets whose uncertainty is well characterised, or for long time intervals less affected by year-to-year variability. Our 68 % uncertainty value is near the 66 % that the IPCC characterises as “likely” for values falling into the $\pm 1\sigma$ interval. The uncertainties reported here combine statistical analysis of the underlying data and expert judgement of the likelihood of results lying outside this range. The limitations of current information are discussed in the paper.

All quantities are presented units of gigatonnes of carbon (GtC, 10¹⁵ gC), which is the same as petagrams of carbon (PgC; Table 1). Units of gigatonnes of CO₂ (or billion tonnes of CO₂) used in policy are equal to 3.664 multiplied by the value in units of GtC.

This paper provides a detailed description of the datasets and methodology used to compute the global carbon budget estimates for the period preindustrial (1750) to 2013 and in more detail for the period 1959 to 2013. We also provide decadal averages starting in 1960 including the last decade (2004–2013), results for the year 2013, and a projection of E_{FF} for year 2014. Finally we provide the total or cumulative emissions

Interactive Discussion

from fossil fuels and land-use change since year 1750, the pre-industrial period, and since year 1870, the reference year for the cumulative carbon estimate used by the Fifth Assessment Report of the Intergovernmental Panel on Climate Change based on the availability of global temperature data (Stocker et al., 2013b). This paper will be updated every year using the format of “living data”, to keep a record of budget versions and the changes in new data, revision of data, and changes in methodology that lead to changes in estimates of the carbon budget. Additional materials associated with the release of each new version will be posted at the Global Carbon Project (GCP) website (<http://www.globalcarbonproject.org/carbonbudget>). Data associated with this release are also available through the Global Carbon Atlas (<http://www.globalcarbonatlas.org>). With this approach, we aim to provide the highest transparency and traceability in the reporting of a set of key indicators and drivers of climate change.

2 Methods

Multiple organizations and research groups around the world generated the original measurements and data used to complete the global carbon budget. The effort presented here is thus mainly one of synthesis, where results from individual groups are collated, analysed and evaluated for consistency. We facilitate access to original data with the understanding that primary datasets will be referenced in future work (See Table 2 for “How to cite” the datasets). Descriptions of the measurements, models, and methodologies follow below and in depth descriptions of each component are described elsewhere (e.g. Andres et al., 2012; Houghton et al., 2012).

This is the ninth version of the “global carbon budget” (see Introduction for details) and the third revised version of the “global carbon budget living data paper”. It is an update of Le Quéré et al. (2014), including data to year 2013 (inclusive) and a projection for fossil fuel emissions for year 2014. The main changes from Le Quéré et al. (2014) are: (1) we use three years of BP energy consumption growth rates (coal, oil, gas) to estimate E_{FF} (Sect. 2.1), (2) we updated S_{OCEAN} estimates from observations to

Interactive Discussion

2013 extending the SOCAT v2 database (Bakker, 2014; Sect. 2.4) with additional new cruises, (3) we introduced results from three atmospheric inverse methods using atmospheric measurements from a global network of surface stations through 2013 that provide a latitudinal breakdown of the combined land and ocean fluxes (Sect. 2.6). The main methodological differences between annual carbon budgets are summarised in Table 3.

2.1 CO₂ emissions from fossil fuel combustion and cement production (E_{FF})

2.1.1 Fossil fuel and cement emissions and their uncertainty

The calculation of global and national CO₂ emissions from fossil fuel combustion, including gas flaring and cement production (E_{FF}), relies primarily on energy consumption data, specifically data on hydrocarbon fuels, collated and archived by several organisations (Andres et al., 2012). These include the Carbon Dioxide Information Analysis Center (CDIAC), the International Energy Agency (IEA), the United Nations (UN), the United States Department of Energy (DoE) Energy Information Administration (EIA), and more recently also the PBL Netherlands Environmental Assessment Agency. We use the emissions estimated by the CDIAC (Boden et al., 2013). The CDIAC emission estimates are the only one that extend back in time to 1751 with consistent and well-documented emissions from fossil fuel combustion, cement production, and gas flaring for all countries and their uncertainty (Andres et al., 1999, 2012, 2014); this makes the dataset a unique resource for research of the carbon cycle during the fossil fuel era.

During the period 1959–2010, the emissions from fossil fuel consumption are based primarily on energy data provided by the UN Statistics Division (Table 4; UN, 2013a, b). When necessary, fuel masses/volumes are converted to fuel energy content using coefficients provided by the UN and then to CO₂ emissions using conversion factors that take into account the relationship between carbon content and energy (heat) content of the different fuel types (coal, oil, gas, gas flaring) and the combustion efficiency

Interactive Discussion

(to account, for example, for soot left in the combustor or fuel otherwise lost or discharged without oxidation). Most data on energy consumption and fuel quality (carbon content and heat content) are available at the country level (UN, 2013a). In general, CO₂ emissions for equivalent primary energy consumption are about 30 % higher for coal compared to oil, and 70 % higher for coal compared to natural gas (Marland et al., 2007). All estimated fossil fuel emissions are based on the mass flows of carbon and assume that the fossil carbon emitted as CO or CH₄, will soon be oxidized to CO₂ in the atmosphere and can be accounted for with CO₂ emissions (see Sect. 2.7).

For the most recent *three years (2011, 2012 and 2013)* when the UN statistics are not yet available, we generated preliminary estimates based on the BP annual energy review by applying the growth rates of energy consumption (coal, oil, gas) for 2011–2013 (BP, 2014) to the CDIAC emissions in 2010. BP's sources for energy statistics overlap with those of the UN data, but are compiled more rapidly using about 70 countries covering about 96 % of global emissions. We use the BP values only for the year-to-year rate of change, because the rates of change are less uncertain than the absolute values and to avoid discontinuities in the time-series when linking the UN-based energy data (up to 2010) with the BP energy data (2011–2013). These preliminary estimates are replaced by the more complete CDIAC data based on UN statistics when they become available. Past experience and work by others (Andres et al., 2014) shows that projections based on the BP rate of change are within the uncertainty provided (see Sect. 3.2 and Supplement from Peters et al., 2013).

Emissions from cement production are based on cement production data from the US Geological Survey up to year 2012 (van Oss, 2013), and up to 2013 for the top 18 countries (representing 85 % of global production; USGS, 2014). For countries without data in 2013 we assume the 2012 values (zero growth). Some fraction of the CaO and MgO in cement is returned to the carbonate form during cement weathering but this is generally regarded to be small and is ignored here.

Emission estimates from gas flaring are calculated in a similar manner as those from solid, liquid, and gaseous fuels, and rely on the UN Energy Statistics to supply the

amount of flared or vented fuel. For emission years 2011–2013, flaring is assumed constant from the emission year 2010 UN-based data. The basic data on gas flaring report atmospheric losses during petroleum production and processing that have large uncertainty and do not distinguish between gas that is flared as CO₂ or vented as CH₄.

5 Fugitive emissions of CH₄ from the so-called upstream sector (e.g., coal mining and natural gas distribution) are not included in the accounts of CO₂ emissions except to the extent that they are captured in the UN energy data and counted as gas “flared or lost”.

10 The published CDIAC dataset has 250 countries and regions included. This expanded list includes countries that no longer exist, such as the USSR or East Pakistan. For the budget, we reduce the list to 216 countries by reallocating emissions to the currently defined territories. This involved both aggregation and disaggregation, and does not change global emissions. Examples of aggregation include merging East and West Germany to the currently defined Germany. Examples of disaggregation include real-
 15 locating the emissions from former USSR to the resulting independent countries. For disaggregation, we use the emission shares when the current territory first appeared. For the most recent years, 2011–2013, the BP statistics are more aggregated, but we retain the detail of CDIAC by applying the growth rates of each aggregated region in the BP dataset to its constituent individual countries in CDIAC.

20 Estimates of CO₂ emissions show that the global total of emissions is not equal to the sum of emissions from all countries. This is largely attributable to emissions that occur in international territory, in particular the combustion of fuels used in international shipping and aviation (bunker fuels), where the emissions are included in the global totals but are not attributed to individual countries. In practice, the emissions
 25 from international bunker fuels are calculated based on where the fuels were loaded, but they are not included with national emissions estimates. Other differences occur because globally the sum of imports in all countries is not equal to the sum of exports and because of differing treatment of oxidation of non-fuel uses of hydrocarbons (e.g. as solvents, lubricants, feedstocks, etc.), and changes in stock (Andres et al., 2012).

Interactive Discussion

The uncertainty of the annual fossil fuel and cement emissions for the globe has been estimated at $\pm 5\%$ (scaled down from the published $\pm 10\%$ at $\pm 2\sigma$ to the use of $\pm 1\sigma$ bounds reported here; Andres et al., 2012). This is consistent with a more detailed recent analysis of uncertainty of $\pm 8.4\%$ at $\pm 2\sigma$ (Andres et al., 2014). This includes an assessment of uncertainties in the amounts of fuel consumed, the carbon and heat contents of fuels, and the combustion efficiency. While in the budget we consider a fixed uncertainty of $\pm 5\%$ for all years, in reality the uncertainty, as a percentage of the emissions, is growing with time because of the larger share of global emissions from non-Annex B countries (emerging economies and developing countries) with less precise statistical systems (Marland et al., 2009). For example, the uncertainty in Chinese emissions has been estimated at around $\pm 10\%$ (for $\pm 1\sigma$; Gregg et al., 2008). Generally, emissions from mature economies with good statistical bases have an uncertainty of only a few per cent (Marland, 2008). Further research is needed before we can quantify the time evolution of the uncertainty, and its temporal error correlation structure. We note that even if they are presented as 1σ estimates, uncertainties of emissions are likely to be mainly country-specific systematic errors related to underlying biases of energy statistics and to the accounting method used by each country. We assign a medium confidence to the results presented here because they are based on indirect estimates of emissions using energy data (Durant et al., 2010). There is only limited and indirect evidence for emissions, although there is a high agreement among the available estimates within the given uncertainty (Andres et al., 2012, 2014), and emission estimates are consistent with a range of other observations (Ciais et al., 2013), even though their regional and national partitioning is more uncertain (Francey et al., 2013).

2.1.2 Emissions embodied in goods and services

National emission inventories take a territorial (production) perspective and “include greenhouse gas emissions and removals taking place within national territory and offshore areas over which the country has jurisdiction” (Rypdal et al., 2006). That is, emis-

sions are allocated to the country where and when the emissions actually occur. The territorial emission inventory of an individual country does not include the emissions from the production of goods and services produced in other countries (e.g. food and clothes) that are used for consumption. Consumption-based emission inventories for an individual country is another attribution point of view that allocates global emissions to products that are consumed within a country, and are conceptually calculated as the territorial emissions less the “embedded” territorial emissions to produce exported products plus the emissions in other countries to produce imported products (Consumption = Territorial – Exports + Imports). The difference between the territorial- and consumption-based emission inventories is the net transfer (exports minus imports) of emissions from the production of internationally traded products. Consumption-based emission attribution results (e.g. Davis and Caldeira, 2010) provide additional information to territorial – based emissions that can be used to understand emission drivers (Hertwich and Peters, 2009), quantify emission (virtual) transfers by the trade of products between countries (Peters et al., 2011b) and potentially design more effective and efficient climate policy (Peters and Hertwich, 2008).

We estimate consumption-based emissions by enumerating the global supply chain using a global model of the economic relationships between sectors within and between every country (Andrew and Peters, 2013; Peters et al., 2011a). Due to availability of the input data, detailed estimates are made for the years 1997, 2001, 2004, and 2007 (using the methodology of Peters et al., 2011b) using economic and trade data from the Global Trade and Analysis Project version 8.1 (GTAP; Narayanan et al., 2013). The results cover 57 sectors and 134 countries and regions. The results are extended into an annual time-series from 1990 to the latest year of the fossil fuel emissions or GDP data (2012 in this budget), using Gross Domestic Product (GDP) data by expenditure in current USD (from the UN National Accounts main Aggregates database; UN, 2014) and time series of trade data from GTAP (based on the methodology in Peters et al. 2011b).

Interactive Discussion

The consumption-based emission inventories in this carbon budget incorporate several improvements over previous versions (Le Quéré et al., 2013; Peters et al., 2011b., 2012b). The detailed estimates for 2004 and 2007 and time series approximation from 1990–2012 are based on an updated version of the GTAP database (Narayanan et al., 2013). We estimate the sector level CO₂ emissions using our own calculations based on the GTAP data and methodology, include flaring and cement emissions from CDIAC, and then scale the national totals (excluding bunker fuels) to match the CDIAC estimates from the most recent carbon budget. We do not include international transportation in our estimates of national totals, but include them in the global total. The time-series of trade data provided by GTAP covers the period 1995–2009 and our methodology uses the trade shares as this dataset. For the period 1990–1994 we assume the trade shares of 1995, while for 2010 and 2011 we assume the trade shares of 2008 since 2009 was heavily affected by the global financial crisis. We identified errors in the trade shares of Taiwan in 2008 and 2009, so its trade shares for 2008–2010 are based on the 2007 trade shares.

We do not provide an uncertainty estimate for these emissions, but based on model comparisons and sensitivity analysis, they are unlikely to be larger than for the territorial emission estimates (Peters et al., 2012a). Uncertainty is expected to increase for more detailed results, and to decrease with aggregation (Peters et al., 2011b; e.g. the results for Annex B will be more accurate than the sector results for an individual country).

The consumption-based emissions attribution method considers the CO₂ emitted to the atmosphere in the production of products, but not the trade in fossil fuels (coal, oil, gas). It is also possible to account for the carbon trade in fossil fuels (Davis et al., 2011), but we do not present that data here. Peters et al. (2012a) additionally considered trade in biomass.

The consumption data do not modify the global average terms in Eq. (1), but are relevant to the anthropogenic carbon cycle as they reflect the trade-driven movement of emissions across the Earth's surface in response to human activities. Furthermore, if national and international climate policies continue to develop in an un-harmonised

way, then the trends reflected in these data will need to be accommodated by those developing policies.

2.1.3 Growth rate in emissions

We report the annual growth rate in emissions for adjacent years (in percent per year) by calculating the difference between the two years and then comparing to the emissions in the first year: $\left[\frac{E_{FF(t_0+1)} - E_{FF(t_0)}}{E_{FF(t_0)}} \times \%yr^{-1} \right]$. This is the simplest method to characterise a one-year growth compared to the previous year and is widely used. *We apply a leap-year adjustment to ensure valid interpretations of annual growth rates. This affects the growth rate by about 0.3% yr⁻¹ ($\frac{1}{365}$) and causes growth rates to go up approximately 0.3% if the first year is a leap year and down 0.3% if the second year is a leap year.*

The relative growth rate of E_{FF} over time periods of greater than one year can be re-written using its logarithm equivalent as follows:

$$\frac{1}{E_{FF}} \frac{dE_{FF}}{dt} = \frac{d(\ln E_{FF})}{dt} \quad (2)$$

Here we calculate relative growth rates in emissions for multi-year periods (e.g. a decade) by fitting a linear trend to $\ln(E_{FF})$ in Eq. (2), reported in percent per year. We fit the logarithm of E_{FF} rather than E_{FF} directly because this method ensures that computed growth rates satisfy Eq. (6). This method differs from previous papers (Canadell et al., 2007; Le Quéré et al., 2009; Raupach et al., 2007) that computed the fit to E_{FF} and divided by average E_{FF} directly, but the difference is very small (<0.05%) in the case of E_{FF} .

2.1.4 Emissions projections using GDP projections

Energy statistics are normally available around June for the previous year. We use the close relationship between the growth in world GDP and the growth in global emissions

Interactive Discussion

(Raupach et al., 2007) to project emissions for the current year. This is based on the so-called Kaya identity (also called IPAT identity for Human Impact (I) on the environment equals the product of $P = \text{Population}$, $A = \text{Affluence}$, $T = \text{Technology}$), whereby E_{FF} is decomposed by the product of GDP and the fossil fuel carbon intensity of the economy (I_{FF}) as follows:

$$E_{\text{FF}} = \text{GDP} \times I_{\text{FF}} \quad (3)$$

Such product-rule decomposition identities imply that the growth rates of the multiplied quantities are additive. Taking a time derivative of Equation (3) gives:

$$\frac{dE_{\text{FF}}}{dt} = \frac{d(\text{GDP} \times I_{\text{FF}})}{dt} \quad (4)$$

and applying the rules of calculus:

$$\frac{dE_{\text{FF}}}{dt} = \frac{d\text{GDP}}{dt} \times I_{\text{FF}} + \text{GDP} \times \frac{dI_{\text{FF}}}{dt} \quad (5)$$

finally, dividing (5) by (3) gives :

$$\frac{1}{E_{\text{FF}}} \frac{dE_{\text{FF}}}{dt} = \frac{1}{\text{GDP}} \frac{d\text{GDP}}{dt} + \frac{1}{I_{\text{FF}}} \frac{dI_{\text{FF}}}{dt} \quad (6)$$

where the left hand term is the relative growth rate of E_{FF} , and the right hand terms are the relative growth rates of GDP and I_{FF} , respectively, which can simply be added linearly to give overall growth rate. The growth rates are reported in percent by multiplying each term by 100. As preliminary estimates of annual change in GDP are made well before the end of a calendar year, making assumptions on the growth rate of I_{FF} allows us to make projections of the annual change in CO_2 emissions well before the end of a calendar year.

2.2 CO₂ emissions from land use, land-use change and forestry (E_{LUC})

LUC emissions reported in the 2014 carbon budget (E_{LUC}) include CO₂ fluxes from deforestation, afforestation, logging (forest degradation and harvest activity), shifting cultivation (cycle of cutting forest for agriculture, then abandoning), and regrowth of forests following wood harvest or abandonment of agriculture. Only some land management activities (Table 5) are included in our LUC emissions estimates (e.g. emissions or sinks related to management and management changes of established pasture and croplands are not included). Some of these activities lead to emissions of CO₂ to the atmosphere, while others lead to CO₂ sinks. E_{LUC} is the net sum of all anthropogenic activities considered. Our annual estimate for 1959–2010 is from a bookkeeping method (Sect. 2.2.1) primarily based on net forest area change and biomass data from the Forest Resource Assessment (FRA) of the Food and Agriculture Organisation (FAO) which is only available at intervals of five years and ends in 2010 (Houghton et al., 2012). Inter-annual variability in emissions due to deforestation and degradation have been coarsely estimated from satellite-based fire activity in tropical forest areas (Sect. 2.2.2; Giglio, 2013; van der Werf et al., 2010). The bookkeeping method is used to quantify the E_{LUC} over the time period of the available data, and the satellite-based deforestation fire information to incorporate interannual variability (E_{LUC} flux annual anomalies) from tropical deforestation fires. The satellite-based deforestation and degradation fire emissions estimates are available for years 1997–2013. We calculate the global annual anomaly in deforestation and degradation fire emissions in tropical forest regions for each year, compared to the 1997–2010 period, and add this annual flux anomaly to the E_{LUC} estimated using the bookkeeping method that is available up to 2010 only and assumed constant at the 2010 value during the period 2011–2013. We thus assume that all land management activities apart from deforestation and degradation do not vary significantly on a year-to-year basis. Other sources of interannual variability (e.g. the impact of climate variability on regrowth fluxes and shifting agriculture CO₂ fluxes) are accounted for in S_{LAND} . In addition, we use results

Interactive Discussion

from nine Dynamic Global Vegetation Models (see Sect. 2.2.3 and Table 6) that calculate net LUC CO₂ emissions in response to observed land cover change reconstructed from observations prescribed to each model, to help quantify the uncertainty in E_{LUC} , and to explore the consistency of our understanding. The three methods are described below, and differences are discussed in Sect. 3.2.

2.2.1 Bookkeeping method

LUC CO₂ emissions are calculated by a bookkeeping method approach (Houghton, 2003) that keeps track of the carbon stored in vegetation and soils before deforestation or other land-use change, and the changes in forest age classes, or cohorts, of disturbed lands after land-use change including possible forest regrowth after deforestation. It tracks the CO₂ emitted to the atmosphere immediately during deforestation, and over time due to the follow-up decay of soil and vegetation carbon in different pools, including wood products pools after logging and deforestation. It also tracks the regrowth of vegetation and associated build-up of soil carbon pools after LUC. It considers transitions between forests, pastures and cropland, shifting cultivation, degradation of forests where a fraction of the trees is removed, abandonment of agricultural land, and forest management such as wood harvest and, in the USA, fire management. In addition to tracking logging debris on the forest floor, the bookkeeping method tracks the fate of carbon contained in harvested wood products that is eventually emitted back to the atmosphere as CO₂, although a detailed treatment of the lifetime in each product pool is not performed (Earles et al., 2012). Harvested wood products are partitioned into three pools with different turnover times. All fuel-wood is assumed burnt in the year of harvest (1.0 yr⁻¹). Pulp and paper products are oxidized at a rate of 0.1 yr⁻¹, timber is assumed to be oxidized at a rate of 0.01 yr⁻¹, and elemental carbon decays at 0.001 yr⁻¹. The general assumptions about partitioning wood products among these pools are based on national harvest data (Houghton, 2003).

The primary land cover change and biomass data for the bookkeeping method analysis is the Forest Resource Assessment of the FAO which provides statistics on forest

cover change and management at intervals of five years (FAO, 2010). The data is based on countries' self-reporting some of which include satellite data in more recent assessments (Table 4). Changes in land cover other than forest are based on annual, national changes in cropland and pasture areas reported by the FAO Statistics Division (FAOSTAT, 2010). LUC country data are aggregated by regions. The carbon stocks on land (biomass and soils), and their response functions subsequent to LUC, are based on FAO data averages per land cover type, per biome and per region. Similar results were obtained using forest biomass carbon density based on satellite data (Baccini et al., 2012). The bookkeeping method does not include land ecosystems' transient response to changes in climate, atmospheric CO₂ and other environmental factors, but the growth/decay curves are based on contemporary data that will implicitly reflect the effects of CO₂ and climate at that time. Results from the bookkeeping method are available from 1850 to 2010.

2.2.2 Fire-based method

LUC associated CO₂ emissions calculated from satellite-based fire activity in tropical forest areas (van der Werf et al., 2010) provide information on emissions due to tropical deforestation and degradation that are complementary to the bookkeeping approach. They do not provide a direct estimate of E_{LUC} as they do not include non-combustion processes such as respiration, wood harvest, wood products or forest regrowth. Legacy emissions such as decomposition from on-ground debris and soils are not included in this method either. However, fire estimates provide some insight in the year-to-year variations in the sub-component of the total E_{LUC} flux that result from immediate CO₂ emissions during deforestation caused, for example, by the interactions between climate and human activity (e.g. there is more burning and clearing of forests in dry years) that are not represented by other methods. The "deforestation fire emissions" assume an important role of fire in removing biomass in the deforestation process, and thus can be used to infer gross instantaneous CO₂ emissions from deforestation using satellite-derived data on fire activity in regions with active deforestation. The method

Interactive Discussion

requires information on the fraction of total area burned associated with deforestation versus other types of fires, and can be merged with information on biomass stocks and the fraction of the biomass lost in a deforestation fire to estimate CO₂ emissions. The satellite-based deforestation fire emissions are limited to the tropics, where fires result mainly from human activities. Tropical deforestation is the largest and most variable single contributor to E_{LUC} .

Fire emissions associated with deforestation and tropical peat burning are based on the Global Fire Emissions Database (GFED) described in van der Werf et al. (2010) but with updated burned area (Giglio, 2013) as well as burned area from relatively small fires that are detected by satellite as thermal anomalies but not mapped by the burned area approach (Randerson, 2012). This information is used as input data in a modified version of the satellite-driven Carnegie Ames Stanford Approach (CASA) biogeochemical model to estimate carbon emissions associated with fires, keeping track of what fraction was due to deforestation (see van der Werf et al., 2010). The CASA model uses different assumptions to compute decay functions compared to the bookkeeping method, and does not include historical emissions or regrowth from land-use change prior to the availability of satellite data. Comparing coincident CO emissions and their atmospheric fate with satellite-derived CO concentrations allows for some validation of this approach (e.g. van der Werf et al., 2008). Results from the fire-based method to estimate LUC emissions anomalies added to the bookkeeping mean E_{LUC} estimate are available from 1997 to 2013. Our combination of LUC CO₂ emissions where the variability of annual CO₂ deforestation emissions is diagnosed from fires assumes that year-to-year variability is dominated by variability in deforestation.

2.2.3 Dynamic Global Vegetation Models (DGVMs)

LUC CO₂ emissions have been estimated using an ensemble of seven DGVMs (from four in the 2012 carbon budget). New model experiments up to year 2013 have been coordinated by the project “Trends and drivers of the regional-scale sources and sinks of carbon dioxide (TRENDY; <http://dgvn.ceh.ac.uk/node/9>)”. We use only models that

have estimated LUC CO₂ emissions and the terrestrial residual sink following the TRENDY protocol (see Sect. 2.5.2), thus providing better consistency in the assessment of the causes of carbon fluxes on land. Models use their latest configurations, summarised in Tables 5 and 6.

The DGVMs were forced with historical changes in land cover distribution, climate, atmospheric CO₂ concentration, and N deposition. As further described below, each historical DGVM simulation was repeated with a time-invariant pre-industrial land cover distribution, allowing to estimate, by difference with the first simulation, the dynamic evolution of biomass and soil carbon pools in response to prescribed land cover change. All DGVMs represent deforestation and (to some extent) regrowth, the most important components of E_{LUC} , but they do not represent all processes resulting directly from human activities on land (Table 5). DGVMs represent processes of vegetation growth, mortality and decomposition associated with natural cycles and include the vegetation and soil response to increasing atmospheric CO₂ levels, to climate variability and change, in addition to atmospheric N deposition in the presence of nitrogen limitation (in four models; Table 5). The DGVMs are independent from the other budget terms except for their use of atmospheric CO₂ concentration to calculate the fertilization effect of CO₂ on primary production.

The DGVMs used a consistent land-use change dataset (Hurtt et al., 2011), which provided annual, half-degree, fractional data on cropland, pasture, primary vegetation and secondary vegetation, as well as all underlying transitions between land-use states, including wood harvest and shifting cultivation. This dataset used the HYDE (Klein Goldewijk et al., 2011) spatially gridded maps of cropland, pasture, and ice/water fractions of each grid cell as an input. The HYDE data is based on annual FAO statistics of change in agricultural area (FAOSTAT, 2010). *For the years 2011, 2012 and 2013*, the HYDE dataset was extrapolated by country for pastures and cropland separately based on the trend in agricultural area over the previous 5 years. The HYDE dataset is independent from the data set used in the bookkeeping method (Houghton, 2003 and updates), which is based primarily on forest area change statistics (FAO, 2010).

Interactive Discussion

Although the Hurtt land-use change dataset indicates whether land-use changes occur on forested or non-forested land, typically only the changes in agricultural areas are used by the models and are implemented differently within each model (e.g. an increased cropland fraction in a grid cell can either be at the expense of grassland, or forest, the latter resulting in deforestation; land cover fractions of the non-agricultural land differ between models). Thus the DGVM forest area and forest area change over time is not consistent with the Forest Resource Assessment of the FAO forest area data used for the book-keeping model to calculate E_{LUC} . Similarly, model-specific assumptions are also applied for the conversion of wood harvest mass or area and other product pools into carbon in some models (Table 5).

The DGVM model runs were forced by either 6 hourly CRU-NCEP or by monthly temperature, precipitation, and cloud cover fields (transformed into incoming surface radiation) based on observations and provided on a $0.5^\circ \times 0.5^\circ$ grid and updated to 2013 (CRU TS3.22; Harris et al., 2014). The forcing data include both gridded observations of climate change and change in global atmospheric CO_2 (Dlugokencky and Tans, 2014), and N deposition (as used in 4 models, Table 5; Lamarque et al., 2010). E_{LUC} is diagnosed in each model by the difference between a model simulation with prescribed historical land cover change and a simulation with constant, pre-industrial land cover distribution. Both simulations were driven by changing atmospheric CO_2 , climate, and in some models N deposition over the period 1860–2013. Using the difference between these two DGVM simulations to diagnose E_{LUC} is not consistent with the definition of E_{LUC} in the bookkeeping method (Gasser and Ciais, 2013; Pongratz et al., 2013). The DGVM approach to diagnose land use change CO_2 emissions is expected to produce systematically higher E_{LUC} emissions than the bookkeeping approach if all the parameters of the two approaches were the same (which is not the case). Here, given the different input data of DGVMs and the bookkeeping approach, this systematic difference cannot be quantified.

2.2.4 Uncertainty assessment for E_{LUC}

Differences between the bookkeeping, the addition of fire-based interannual variability to the bookkeeping, and DGVM methods originate from three main sources: the land cover change data set, different approaches in models, and in the different processes represented (Table 5). We examine the results from the nine DGVM models and of the bookkeeping method to assess the uncertainty in E_{LUC} .

The uncertainties in the annual E_{LUC} estimates are examined using the standard deviation across models, which ranged from 0.3 to 1.1 GtC yr⁻¹, with an average of 0.7 GtC yr⁻¹ from 1959 to 2013 (Table 7). The mean of the multi-model E_{LUC} estimates is the same as the mean of the bookkeeping estimate from the budget (Eq. 1) at 1.3 GtC for 1959 to 2010. The multi-model mean and bookkeeping method differ by less than 0.5 GtC yr⁻¹ over 90 % of the time. Based on this comparison, we assess that an uncertainty of ± 0.5 GtC yr⁻¹ provides a semi-quantitative measure of uncertainty for annual emissions, and reflects our best value judgment that there is at least 68 % chance ($\pm 1\sigma$) that the true LUC emission lies within the given range, for the range of processes considered here. This is consistent with the analysis of Houghton et al. (2012), which partly reflects improvements in data on forest area change using satellite data, and partly more complete understanding and representation of processes in models.

The uncertainties in the decadal mean estimates from the DGVM ensemble are likely correlated between decades, and thus we apply the annual uncertainty as a measure of the decadal uncertainty. The correlations between decades come from (1) common biases in system boundaries (e.g. not counting forest degradation in some models); (2) common definition for the calculation of E_{LUC} from the difference of simulations with and without LUC (a source of bias vs. the unknown truth); (3) common and uncertain land-cover change input data which also cause a bias, though if a different input dataset is used each decade, decadal fluxes from DGVMs may be partly decorrelated; (4) model structural errors (e.g. systematic errors in biomass stocks). In addition, errors arising from uncertain DGVM parameter values would be random but they are not ac-

counted for in this study, since no DGVM provided an ensemble of runs with perturbed parameters.

Prior to 1959, the uncertainty in E_{LUC} is taken as $\pm 33\%$, which is the ratio of uncertainty to mean from the 1960s (Table 7), the first decade available. This ratio is consistent with the mean standard deviation of DGMVs LUC emissions over 1870–1958 (0.41 GtC) over the multi-model mean (0.94 GtC).

2.3 Atmospheric CO₂ growth rate (G_{ATM})

2.3.1 Global atmospheric CO₂ growth rate estimates

The atmospheric CO₂ growth rate is provided by the US National Oceanic and Atmospheric Administration Earth System Research Laboratory (NOAA/ESRL; Dlugokencky and Tans, 2014), which is updated from Ballantyne et al. (2012). For the 1959–1980 period, the global growth rate is based on measurements of atmospheric CO₂ concentration averaged from the Mauna Loa and South Pole stations, as observed by the CO₂ Program at Scripps Institution of Oceanography (Keeling et al., 1976). For the 1980–2012 time period, the global growth rate is based on the average of multiple stations selected from the marine boundary layer sites with well-mixed background air (Ballantyne et al., 2012), after fitting each station with a smoothed curve as a function of time, and averaging by latitude band (Masarie and Tans, 1995). The annual growth rate is estimated from atmospheric CO₂ concentration by taking the average of the most recent December-January months corrected for the average seasonal cycle and subtracting this same average one year earlier. The growth rate in units of ppm yr⁻¹ is converted to fluxes by multiplying by a factor of 2.120 GtC per ppm (Prather et al., 2012) for comparison with the other components.

The uncertainty around the annual growth rate based on the multiple stations dataset ranges between 0.11 and 0.72 GtC yr⁻¹, with a mean of 0.60 GtC yr⁻¹ for 1959–1980 and 0.19 GtC yr⁻¹ for 1980–2013, when a larger set of stations were available. It is based on the number of available stations, and thus takes into account both the mea-

surement errors and data gaps at each station. This uncertainty is larger than the uncertainty of $\pm 0.1 \text{ GtC yr}^{-1}$ reported for decadal mean growth rate by the IPCC because errors in annual growth rate are strongly anti-correlated in consecutive years leading to smaller errors for longer time scales. The decadal change is computed from the difference in concentration ten years apart based on a measurement error of 0.35 ppm. This error is based on offsets between NOAA/ESRL measurements and those of the World Meteorological Organization World Data Center for Greenhouse Gases (NOAA/ESRL, 2014) for the start and end points (the decadal change uncertainty is the $\sqrt{(2(0.35 \text{ ppm})^2)}(10 \text{ yr})^{-1}$ assuming that each yearly measurement error is independent). This uncertainty is also used in Table 8.

The contribution of anthropogenic CO and CH₄ is neglected from the global carbon budget (see Sect. 2.7.1). We assign a high confidence to the annual estimates of G_{ATM} because they are based on direct measurements from multiple and consistent instruments and stations distributed around the world (Ballantyne et al., 2012).

In order to estimate the total carbon accumulated in the atmosphere since 1750 or 1870, we use an atmospheric CO₂ concentration of $277 \pm 3 \text{ ppm}$ or $288 \pm 3 \text{ ppm}$, respectively, based on a cubic spline fit to ice core data (Joos and Spahni, 2008). The uncertainty of $\pm 3 \text{ ppm}$ (converted to $\pm 1\sigma$) is taken directly from the IPCC's assessment (Ciais et al., 2013). Typical uncertainties in the atmospheric growth rate from ice core data are $\pm 1\text{--}1.5 \text{ GtC per decade}$ as evaluated from the Law Dome data (Etheridge et al., 1996) for individual 20-year intervals over the period from 1870 to 1960 (Bruno and Joos, 1997).

2.4 Ocean CO₂ sink

Estimates of the global ocean CO₂ sink are based on a combination of a mean CO₂ sink estimate for the 1990s from observations, and a trend and variability in the ocean CO₂ sink for 1959–2013 from *seven* global ocean biogeochemistry models. *We use*

three observation-based estimates of S_{OCEAN} available for the recent decade(s) to provide a qualitative assessment of confidence in the reported results.

2.4.1 Observation-based estimates

A mean ocean CO_2 sink of $2.2 \pm 0.4 \text{ GtC yr}^{-1}$ for the 1990s was estimated by the IPCC (Denman et al., 2007) based on indirect observations and their spread: ocean/land CO_2 sink partitioning from observed atmospheric O_2/N_2 concentration trends (Manning and Keeling, 2006), an oceanic inversion method constrained by ocean biogeochemistry data (Mikaloff Fletcher et al., 2006), and a method based on penetration time scale for CFCs (McNeil et al., 2003). This is comparable with the sink of $2.0 \pm 0.5 \text{ GtC yr}^{-1}$ estimated by Khatiwala et al. (2013) for the 1990s, and with the sink of 1.9 to 2.5 estimated from a range of methods for the period 1990–2009 (Wanninkhof et al., 2013), with uncertainties ranging from $\pm 0.3 \text{ GtC yr}^{-1}$ to $\pm 0.7 \text{ GtC yr}^{-1}$. *The most direct way for estimating the observation-based ocean sink is from the product of (sea-air $p\text{CO}_2$ difference) \times (gas transfer coefficient). Estimates based on sea-air $p\text{CO}_2$ are fully consistent with indirect observations (Zeng et al., 2005), but their uncertainty is larger mainly due to difficulty in capturing complex turbulent processes in the gas transfer coefficient (Sweeney et al., 2007).*

Two of the three observation-based estimates computed the interannual variability in the ocean CO_2 sink using interpolated measurements of surface ocean fugacity of CO_2 ($p\text{CO}_2$ corrected for the non-ideal behaviour of the gas; Pfeil et al., 2013). The measurements were from the Surface Ocean CO_2 Atlas (SOCAT v2; Bakker, 2014) that contains data to the end of 2011. This was extended with 2.4 million additional measurements from 2012 and 2013 from all basins (see data attribution table in Appendix A), submitted to SOCAT but not yet fully quality controlled following standard SOCAT procedures. Revisions and corrections to measurements from before 2012 were also included where they were available. Here all new data were subjected to an automated quality control system to detect and remove the most obvious errors (e.g. incorrect reporting of metadata such as position, wrong units, clearly unrealistic

Interactive Discussion

data etc.). The combined SOCAT v2 and preliminary 2012–2013 data were used with an inversion method (Rödenbeck et al., 2013) and a combined self-organising map and feed-forward neural network (Landschützer et al., 2014). The observation-based estimates were corrected to remove a background (not part of anthropogenic ocean flux) ocean source of CO₂ to the atmosphere of 0.45 GtC yr⁻¹ from riverine input to the ocean (Jacobson et al., 2007), to make them comparable to S_{OCEAN} which only represents the annual uptake of anthropogenic CO₂ by the ocean.

We also compare the results with those of Park et al. (2010) based on regional correlations between surface temperature and pCO₂, changes in surface temperature observed by satellite, and wind speed estimates also from satellite data for 1990–2009 (Atlas et al., 2011). The product of Park et al. (2010) provides a data-based assessment of the interannual variability combined with a model-based assessment of the trend and mean in S_{OCEAN}. Several other data-based products are in preparation (e.g. Zeng, 2014) and the comparison with data products should help constrain the ocean CO₂ sink in the future.

We use the data-based product of Khatiwala et al. (2009) updated by Khatiwala et al. (2013) to estimate the anthropogenic carbon accumulated in the ocean during 1765–1958 (60.2 GtC) and 1870–1958 (47.5 GtC), and assume an oceanic uptake of 0.4 GtC for 1750–1765 where no data are available based on the mean uptake during 1765–1770. The estimate of Khatiwala et al. (2009) is based on regional disequilibrium between surface pCO₂ and atmospheric CO₂, and a Green's function utilizing transient ocean tracers like CFCs and ¹⁴C to ascribe changes through time. It does not include changes associated with changes in ocean circulation, temperature and climate, but these are thought to be small over the time period considered here (Ciais et al., 2013). The uncertainty in cumulative uptake of ±20 GtC (converted to ±1σ) is taken directly from the IPCC's review of the literature (Rhein et al., 2013), or about ±30 % for the annual values (Khatiwala et al., 2009).

2.4.2 Global Ocean Biogeochemistry models

The trend in the ocean CO₂ sink for 1959–2013 is computed using a combination of seven global ocean biogeochemistry models (Table 6). The models represent the physical, chemical and biological processes that influence the surface ocean concentration of CO₂ and thus the air-sea CO₂ flux. The models are forced by meteorological re-analysis and atmospheric CO₂ concentration data available for the entire time period. Models do not include the effects of anthropogenic changes in nutrient supply. They compute the air-sea flux of CO₂ over grid boxes of 1 to 4° in latitude and longitude. The ocean CO₂ sink for each model is normalised to the observations, by dividing the annual model values by their observed average over 1990–1999 (obtained from Manning and Keeling, 2006; McNeil et al., 2003; Mikaloff Fletcher et al., 2006), and multiplying this with the observation-based estimate of 2.2 GtC yr⁻¹. The ocean CO₂ sink for each year (*t*) is therefore:

$$S_{\text{OCEAN}}(t) = \frac{1}{n} \sum_{m=1}^{m=n} \frac{S_{\text{OCEAN}}^m(t)}{S_{\text{OCEAN}}^m(1990 - 1999)} \times 2.2 \quad (7)$$

where *n* is the number of models. This normalisation ensures that the ocean CO₂ sink for the global carbon budget is based on observations, whereas the trends and annual values in CO₂ sinks are from model estimates. The normalisation based on a ratio assumes that if models over or underestimate the sink in the 1990s, it is primarily due to the process of diffusion, which depends on the gradient of CO₂. Thus a ratio is more appropriate than an offset as it takes into account the time-dependence of CO₂ gradients in the ocean. The mean uncorrected ocean CO₂ sink from the seven models for 1990–1999 ranges between 1.5 and 2.6 GtC yr⁻¹, with a multi model mean of 1.9 GtC yr⁻¹.

2.4.3 Uncertainty assessment for S_{OCEAN}

The uncertainty around the mean ocean sink of anthropogenic CO_2 was already quantified for the 1990s (see Sect. 2.4.1). To quantify the uncertainty around annual values, we examine the standard deviation of the normalised model ensemble. We use further information from the three data-based products to assess the confidence level. The standard deviation of the ocean model ensemble averages to 0.15 GtC yr^{-1} during 1980–2010 (with a maximum of 0.22), but it increases as the model ensemble goes back in time, with a standard deviation of 0.28 GtC yr^{-1} across models in the 1960s. We estimate that the uncertainty in the annual ocean CO_2 sink is about $\pm 0.5 \text{ GtC yr}^{-1}$ from the fractional uncertainty of the data uncertainty of $\pm 0.4 \text{ GtC yr}^{-1}$ and standard deviation across models of up to $\pm 0.28 \text{ GtC yr}^{-1}$, reflecting both the uncertainty in the mean sink from observations during the 1990's (Denman et al., 2007; Sect. 2.4.1) and in the interannual variability as assessed by models.

We examine the consistency between the variability of the model-based and the data-based products to assess confidence in S_{OCEAN} . The interannual variability of the ocean fluxes (quantified as the standard deviation) of the three data-based estimates for 1990–2009 (when they overlap) is $\pm 0.37 \text{ GtC yr}^{-1}$ (Rödenbeck et al., 2014), $\pm 0.25 \text{ GtC yr}^{-1}$ (Landschützer et al., 2014), and $\pm 0.14 \text{ GtC yr}^{-1}$ (Park et al., 2010), compared to $\pm 0.18 \text{ GtC yr}^{-1}$ for the model mean. The standard deviation includes a component of trend and decadal variability in addition to interannual variability, and their relative influence differs across estimates. The phase is generally consistent between estimates, with a higher ocean CO_2 sink during El Niño events. The annual data-based estimates correlate with the ocean CO_2 sink estimated here with a correlation of $r = 0.36$ (0.0 to 0.49 for individual models), $r = 0.73$ (0.54 to 0.68), and $r = 0.64$ (0.12 to 0.71) for the data-based estimates of Rödenbeck et al. (2014), Landschützer et al. (2014), and Park et al. (2010), respectively (simple linear regression), but their mutual correlation ranges between 0.24 and 0.31 only. The use of annual data for the correlation may reduce the correlation because the dominant source of variability asso-

ciated with El Niño events is less than one year. We assess a medium confidence level to the annual ocean CO₂ sink and its uncertainty because they are based on multiple lines of evidence, and *the results are consistent in that the interannual variability in the model and data-based estimates are all generally small compared to the variability in atmospheric CO₂ growth rate. Nevertheless the various results do not show high agreement in amplitude on the global scale and for the relative roles of the annual and decadal variability compared to the trend.*

2.5 Terrestrial CO₂ sink

The difference between the fossil fuel (E_{FF}) and LUC net emissions (E_{LUC}), the growth rate in atmospheric CO₂ concentration (G_{ATM}) and the ocean CO₂ sink (S_{OCEAN}) is attributable to the net sink of CO₂ in terrestrial vegetation and soils (S_{LAND}), within the given uncertainties. Thus, this sink can be estimated either as the residual of the other terms in the mass balance budget but also directly calculated using DGVMs or estimated from inverse models that close a spatiotemporally explicit form of the mass-balance in Eq. (1). The residual land sink (S_{LAND}) is thought to be in part because of the fertilising effect of rising atmospheric CO₂ on plant growth, N deposition and climate change effects such as the lengthening of the growing season in northern temperate and boreal areas. S_{LAND} does not include gross land sinks directly resulting from LUC (e.g. regrowth of vegetation) as these are estimated as part of the net land use flux (E_{LUC}). System boundaries make it difficult to attribute exactly CO₂ fluxes on land between S_{LAND} and E_{LUC} (Erb et al., 2013), and by design most of the uncertainties in our method are allocated to S_{LAND} for those processes that are poorly known or represented in models.

2.5.1 Residual of the budget

For 1959–2013, the terrestrial carbon sink was estimated from the residual of the other budget terms by rearranging Eq. (1):

$$S_{\text{LAND}} = E_{\text{FF}} + E_{\text{LUC}} - (G_{\text{ATM}} + S_{\text{OCEAN}}) \quad (8)$$

The uncertainty in S_{LAND} is estimated annually from the root sum of squares of the uncertainty in the right-hand terms assuming the errors are not correlated. The uncertainty averages to $\pm 0.8 \text{ GtC yr}^{-1}$ over 1959–2013 (Table 7). S_{LAND} estimated from the residual of the budget includes, by definition, all the missing processes and potential biases in the other components of Eq. (8).

2.5.2 DGVMs

A comparison of the residual calculation of S_{LAND} in Eq. (8) with its estimates from the same DGVMs used to estimate E_{LUC} in Sect. 2.2.3, but here excluding the effects of changes in land cover (using a constant pre-industrial land cover distribution), provides an independent estimate of the consistency of S_{LAND} with our understanding of the functioning of the terrestrial vegetation in response to CO_2 and climate variability (Table 7). As described in Sect. 2.2.3, the DGVM runs that exclude the effects of changes in land cover include all climate variability and CO_2 effects over land, but do not include reductions in CO_2 sink capacity associated with human activity directly affecting changes in vegetation cover and management, which by design is allocated to E_{LUC} . This effect has been estimated to have led to a reduction in the terrestrial sink by 0.5 GtC yr^{-1} since 1750 (Gitz and Ciais, 2003). The models in this configuration estimate the mean and variability of S_{LAND} based on atmospheric CO_2 and climate, and thus both terms can be compared to the budget residual.

The multi-DGVM mean of $2.5 \pm 1.0 \text{ GtC yr}^{-1}$ for the period 2004–2013 agrees well with the value computed from the budget residual (Table 7). The standard deviation of the annual CO_2 sink across the nine DGVMs ranges from ± 0.4 to $\pm 1.4 \text{ GtC yr}^{-1}$, with a

Interactive Discussion

mean standard deviation of $\pm 0.9 \text{ GtC yr}^{-1}$ for the period 1959 to 2013. The model mean correlates with the budget residual with $r = 0.71$, compared to correlations of $r = 0.46$ to $r = 0.70$ (median of 0.61) between individual models. The standard deviation is similar to that of the five model ensembles presented in Le Quéré et al. (2009), but the correlation is improved compared to $r = 0.54$ obtained in the earlier study. The DGVM results suggest that the sum of our knowledge on annual CO_2 emissions and their partitioning is plausible (see Discussion), and provide insight on the underlying processes and regional breakdown. However as the standard deviation across the DGVMs (of $\pm 0.9 \text{ GtC yr}^{-1}$) is of the same magnitude as the combined uncertainty due to the other components (E_{FF} , E_{LUC} , G_{ATM} , S_{OCEAN} ; Table 7), the DGVMs do not provide further reduction of uncertainty on the terrestrial CO_2 sink compared to the residual of the budget (Eq. 8). Yet, DGVM results are largely independent from the residual of the budget, and it is worth noting that the residual method and ensemble mean DGVM results are consistent within their respective uncertainties. We assess a medium confidence level to the annual land CO_2 sink and its uncertainty because the estimates from the residual budget and averaged DGVMs match well within their respective uncertainties, and the estimates based on the residual budget are primarily dependent on E_{FF} and G_{ATM} , both of which are well constrained.

2.6 View from the atmosphere

The world-wide network of atmospheric measurements can be used with atmospheric inversion methods to constrain the location of the combined surface CO_2 fluxes from all sources, including fossil and LUC emissions and land and ocean CO_2 sinks. As the geographical distribution of fossil fuel emissions is already known, it can be removed from the signal to provide a view from the atmosphere of the CO_2 fluxes over land and over the ocean. Here we used preliminary atmospheric CO_2 data to the end of 2013, and three atmospheric CO_2 inversions (Table 6) to infer the total CO_2 flux over land regions, and the distribution of the total land + ocean CO_2 fluxes for the North, Tropics

Interactive Discussion

and South. We focus here on the largest and most consistent sources of information, and use these estimates to comment on the consistency across various data streams and process-based estimates.

2.6.1 Atmospheric inversions

5 The three inversion systems used in this release (Chevallier, 2005; Peters, 2010; Rödenbeck, 2005) are based on the same Bayesian inversion principles and interpret mostly the same observed time series (or subsets thereof), but use different methodologies that represent a cross-cut of the many approaches used in the field. This concerns the time resolution of the estimates (weekly, monthly), their spatial breakdown (grid size), their assumed correlation structures, and the mathematical approach (4d-VAR, EnKF). The details of these approaches are documented extensively in the references provided. Most importantly, each system has used a different atmospheric transport model, which was demonstrated to be a driving factor behind differences in atmospheric-based flux estimates, and specifically their global distribution (Stephens et al., 2007). Most inverse models use prior estimates for the ocean and land-biosphere, sometimes very similar to those used in Sects. 2.4.1 and 2.5.1 above to assign prior fluxes. They do not separately estimate E_{FF} but rather use similar data sources as described in Sects. 2.1.1, and 2.2.2 above to set these. Finally atmospheric inversions include CO_2 fluxes from rivers (which need to be taken into account in the comparison to the other information sources), and chemical oxidation of reactive carbon-containing gases (which are neglected here). These inverse estimates are not truly independent of the other estimates presented here because the atmospheric observations encompass the set of atmospheric observations used for the global growth rate (Sect. 2.3). However they provide new information on the regional distribution of the fluxes.

25 In this first carbon budget release including inverse models we focus the analysis on two known strengths of the inverse approach: the derivation of year-to-year changes in total land ($E_{LUC} + S_{LAND}$) fluxes consistent with the whole network of atmospheric observations, and the spatial breakdown of land and ocean fluxes ($E_{LUC} + S_{LAND} + S_{OCEAN}$)

across large regions of the globe. The total land flux correlate well with those estimated from the budget residual (Eq. 1) with correlations ranging from $r = 0.84$ to 0.93 , and with the DGVM multi-model mean with correlations ranging from $r = 0.71$ to 0.84 ($r = 0.37$ to 0.82 for individual DGVMs and inversions). The spatial breakdown is discussed in Sect. 3.1.3.

2.7 Processes not included in the global carbon budget

2.7.1 Contribution of anthropogenic CO and CH₄ to the global carbon budget

Anthropogenic emissions of CO and CH₄ to the atmosphere are eventually oxidized to CO₂ and thus are part of the global carbon budget. These contributions are omitted in Eq. (1), but an attempt is made in this section to estimate their magnitude, and identify the sources of uncertainty. Anthropogenic CO emissions are from incomplete fossil fuel and biofuel burning and deforestation fires. The main anthropogenic emissions of fossil CH₄ that matter for the global carbon budget are the fugitive emissions of coal, oil and gas upstream sectors (see below). These emissions of CO and CH₄ contribute a net addition of fossil carbon to the atmosphere.

In our estimate of E_{FF} we assumed (Sect. 2.1.1) that all the fuel burned is emitted as CO₂, thus CO anthropogenic emissions and their atmospheric oxidation into CO₂ within a few months are already counted implicitly in E_{FF} and should not be counted twice (same for ELUC and anthropogenic CO emissions by deforestation fires). Anthropogenic emissions of fossil CH₄ are not included in E_{FF} , because these fugitive emissions are not included in the fuel inventories. Yet they contribute to the annual CO₂ growth rate after CH₄ gets oxidized into CO₂. Anthropogenic emissions of fossil CH₄ represent 15% of total CH₄ emissions (Kirschke et al., 2013) that is 61 Tg C yr⁻¹ for the past decade. Assuming steady state, these emissions are all converted to CO₂ by OH oxidation, and thus explain 0.06 PgC yr⁻¹ of the global CO₂ growth rate in the past decade.

Interactive Discussion

Other anthropogenic changes in the sources of CO and CH₄ from wildfires, biomass, wetlands, ruminants or permafrost changes are similarly assumed to have a small effect on the CO₂ growth rate.

2.7.2 Anthropogenic carbon fluxes in the land to ocean continuum

The approach used to determine the global carbon budget considers only anthropogenic CO₂ emissions and their partitioning among the atmosphere, ocean and land. In this analysis, the land and ocean reservoirs that take up anthropogenic CO₂ from the atmosphere are conceived as independent carbon storage repositories. This approach thus omits that carbon is continuously displaced along the land-ocean aquatic continuum (LOAC) comprising freshwaters, estuaries and coastal areas. Carbon is transferred both in inorganic (bicarbonates and dissolved CO₂), and organic (dissolved and particulate organic carbon) forms along this continuum (Bauer et al., 2013). During its journey from upland terrestrial ecosystems to the oceans, carbon is not only transferred laterally, but is also sequestered in e.g. freshwater and coastal sediments (Krumins et al., 2013; Tranvik et al., 2009) or released back to the atmosphere, mainly as respired CO₂ (Aufdenkampe et al., 2011; Battin et al., 2009; Cole et al., 2007; Laruelle et al., 2010; Regnier et al., 2013), and to a much lesser extent, as CH₄ (Bastviken et al., 2011; Borges and Abril, 2011). A significant fraction of this lateral carbon flux is entirely “natural” and is thus a steady state component of the pre-industrial carbon cycle that can be ignored in the current analysis. The remaining fraction is anthropogenic carbon entrained into the lateral transport loop of the LOAC, a perturbation that is relevant for the global carbon budget presented here.

The recent synthesis by Regnier et al. (2013) is the first attempt to estimate the anthropogenic component of LOAC carbon fluxes and their significance for the global carbon budget. The results of their analysis can be summarized in three points of relevance to the budget. First, only a portion of the anthropogenic CO₂ taken up by land ecosystems is sequestered in soil and biomass pools, as $1 \pm 0.5 \text{ GtC yr}^{-1}$ is exported to the LOAC. This flux is comparable to the C released to the atmosphere by LUC (Ta-

Global Carbon Budget 2014

C. Le Quéré et al.

[Title Page](#)[Abstract](#)[Instruments](#)[Data Provenance & Structure](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

ble 8). Second, the exported anthropogenic carbon is both stored ($0.55 \pm 0.3 \text{ GtC yr}^{-1}$) and released back to the atmosphere as CO_2 ($0.35 \pm 0.2 \text{ GtC yr}^{-1}$), the magnitude of these fluxes resulting from the combined effects of freshwaters, estuaries and coastal seas. Third, a small fraction of anthropogenic carbon displaced by the LOAC accumulates in the open ocean ($0.1 \pm > 0.05 \text{ GtC yr}^{-1}$). The anthropogenic perturbation of the carbon fluxes from land to ocean does not contradict the method used in Sect. 2.5 to define the ocean sink and residual land sink. However, it does point to the need to account for the fate of anthropogenic carbon once it is removed from the atmosphere by land ecosystems (summarized in Fig. 2). In theory, direct estimates of changes of the ocean inorganic carbon inventory over time would see the land flux of anthropogenic carbon and would thus have a bias relative to air-sea flux estimates and tracer based reconstructions. However, currently the value is small enough to be not noticeable relative to the errors in the individual techniques.

More importantly the residual land sink (here land being terrestrial ecosystems) calculated in a budget which accounts for the LOAC ($3.25 \pm 0.9 \text{ GtC yr}^{-1}$) is larger than the residual land sink (S_{LAND}) value of $2.9 \pm 0.8 \text{ GtC yr}^{-1}$ (2004–2013) reported in Table 8. This is because this flux is partially offset by a net source of CO_2 to the atmosphere of $0.35 \pm 0.3 \text{ GtC yr}^{-1}$ from rivers, estuaries and coastal seas. In addition, because anthropogenic CO_2 taken up by land ecosystems is exported to the LOAC, the annual land carbon storage change (1.35 GtC yr^{-1}) is notably smaller than the residual uptake by land ecosystems (S_{LAND}) calculated in the GCP budget (2.9 GtC yr^{-1}), a significant fraction of the displaced carbon (0.65 GtC yr^{-1}) from land ecosystems that is stored in freshwater and coastal sediments (0.55 GtC yr^{-1}), and to a lesser extent, in the open ocean (0.1 GtC yr^{-1}).

All estimates of LOAC are given with low confidence, because they originate from a single source. The carbon budget presented here implicitly incorporates the fluxes from the LOAC with S_{LAND} . We do not attempt to separate these fluxes because the uncertainties in either estimate are too large, and there is insufficient information available to estimate the LOAC fluxes on an annual basis.

3 Results

3.1 Global carbon budget averaged over decades and its variability

The global carbon budget averaged over the last decade (2004–2013) is shown in Fig. 2. For this time period, 91 % of the total emissions ($E_{\text{FF}} + E_{\text{LUC}}$) were caused by fossil fuel combustion and cement production, and 9 % by land-use change. The total emissions were partitioned among the atmosphere (44 %), ocean (26 %) and land (29 %). All components except land-use change emissions have grown since 1959 (Figs. 3 and 4), with important interannual variability in the atmospheric growth rate and in the land CO_2 sink (Fig. 4), and some decadal variability in all terms (Table 8).

3.1.1 CO_2 emissions

Global CO_2 emissions from fossil fuel combustion and cement production have increased every decade from an average of $3.1 \pm 0.2 \text{ GtC yr}^{-1}$ in the 1960s to an average of $8.9 \pm 0.4 \text{ GtC yr}^{-1}$ during 2004–2013 (Table 8 and Fig. 5). The growth rate in these emissions decreased between the 1960s and the 1990s, from $4.5 \% \text{ yr}^{-1}$ in the 1960s (1960–1969), $2.9 \% \text{ yr}^{-1}$ in the 1970s (1970–1979), $1.9 \% \text{ yr}^{-1}$ in the 1980s (1980–1989), $1.0 \% \text{ yr}^{-1}$ in the 1990s (1990–1999), and began increasing again in the 2000s at an average growth rate of $3.3 \% \text{ yr}^{-1}$, decreasing slightly, to $2.5 \% \text{ yr}^{-1}$ for the last decade (2004–2013). In contrast, CO_2 emissions from LUC have remained constant at around $1.5 \pm 0.5 \text{ GtC yr}^{-1}$ between 1960–1999, and decreased to $0.9 \pm 0.5 \text{ GtC yr}^{-1}$ during 2004–2013. The E_{LUC} estimates from the bookkeeping method and the DGVM models are consistent within their respective uncertainties (Table 7 and Fig. 6). The decrease in emissions from LUC since 2000 is reproduced by the DGVMs (Fig. 6).

Interactive Discussion

3.1.2 Partitioning

The growth rate in atmospheric CO₂ increased from $1.7 \pm 0.1 \text{ GtC yr}^{-1}$ in the 1960s to $4.3 \pm 0.1 \text{ GtC yr}^{-1}$ during 2004–2013 with important decadal variations (Table 8). Both ocean and land CO₂ sinks increased roughly in line with the atmospheric increase, but with significant decadal variability on land (Table 8). The ocean CO₂ sink increased from $1.1 \pm 0.5 \text{ GtC yr}^{-1}$ in the 1960s to $2.6 \pm 0.5 \text{ GtC yr}^{-1}$ during 2004–2013, with interannual variations of the order of a few tenths of GtC yr^{-1} generally showing an increased ocean sink during El Niño events (Fig. 7). Although there is some coherence between the ocean models and data products and among data products, their mutual correlation are weak and highlight disagreement on the exact amplitude of the interannual variability, and on the relative importance of the trend versus the variability (Sect. 2.4.3 and Fig. 7). Most estimates produce a mean CO₂ sink for the 1990s that is below the mean assessed by the IPCC from indirect (but arguably more reliable) observations (Sect. 2.4.1). This could reflect issues with the vertical diffusion in ocean models, though as data-products also support a lower mean CO₂ sink, this may also suggest a need to reassess the mean carbon sinks.

The land CO₂ sink increased from $1.8 \pm 0.7 \text{ GtC yr}^{-1}$ in the 1960s to $2.9 \pm 0.8 \text{ GtC yr}^{-1}$ during 2004–2013, with important interannual variations of up to 2 GtC yr^{-1} generally showing a decreased land sink during El Niño events, overcompensating the increased in ocean sink and accounting for the enhanced atmospheric growth rate during El Niño events (Poulter et al., 2014). The high uptake anomaly around year 1991 is thought to be caused by the effect of the volcanic eruption of Mount Pinatubo on climate (Mercado et al., 2009) and is not generally reproduced by the DGVMs but assigned to S_{LAND} by the two inverse systems that include this period (Fig. 6). The larger land CO₂ sink during 2004–2013 compared to the 1960s is reproduced by all the DGVMs in response to combined atmospheric CO₂ increase and climate change and variability (average change of 1.4 GtC yr^{-1} ; eight models ranging between 0.8 and 2.3 GtC yr^{-1} with one model at 0.1 GtC yr^{-1}), consistent with the

budget residual and reflecting a common knowledge of the processes (Table 7). The decadal change is also consistent with the results from the atmospheric inversions who estimate a trend of 0.84 and 0.62 GtC yr⁻¹ per decade, for the inversions of Chevallier et al. (2005) and Rödenbeck et al. (2003), respectively.

The total CO₂ fluxes on land ($E_{LUC} + S_{LAND}$) constrained by the atmospheric inversions show in general very good agreement with the global budget estimate, as expected given the strong constraint of G_{ATM} and the small relative uncertainty typically assumed on S_{OCEAN} and E_{FF} by inversions. The total sink is of similar magnitude for the decadal average, with estimates from the inversions of 1.7, 2.0 and 3.1 GtC yr⁻¹ compared 2.0 ± 0.6 GtC yr⁻¹ for the budget residual (Tables 7). The inversions total land sink would be 1.2, 1.5, and 2.6 GtC yr⁻¹ when including a mean river flux correction of 0.45 GtC yr⁻¹, though the exact correction would be smaller when taking into account the anthropogenic contribution to river fluxes (Sect. 2.7.2). The IAV of the inversions also matches the residual-based S_{LAND} closely (Fig. 6). The multi-model mean from the DGVM ensemble that performed LUC simulations also compare well with the estimate from the residual budget and atmospheric inversions, with a decadal mean of 1.4 ± 0.9 GtC yr⁻¹ (Table 7), although individual models differ by several GtC for some years (Fig. 6).

3.1.3 Distribution

The total surface CO₂ fluxes on land and ocean including LUC ($E_{LUC} + S_{LAND} + S_{OCEAN}$) distributed regionally by latitude band according to atmospheric inversions show some consistency across regions and methods. In the South (south of 30° S), the atmospheric inversions and combined models all suggest a CO₂ sink between 1.3 and 1.6 GtC yr⁻¹, increasing with time (Fig. 8), although the details of the interannual variability is not consistent across methods. The interannual variability in the South is low because of the dominance of ocean area with low variability compared to land areas. In the tropics (30° S–30° N), both the atmospheric inversions and combined models

Interactive Discussion

suggest the carbon balance in this region is close to neutral over the past decade. It is also the source of the largest variability, both at the interannual time scale but also with large decadal variability. Finally in the North (north of 30° N), the inversions and combined models disagree on the magnitude of the CO₂ sink with the ensemble mean of the process models suggesting a smaller total Northern Hemisphere sink of 2.1 ± 0.6 GtC yr⁻¹ while the inversions estimate a sink of between 2.4 and 3.5 GtC yr⁻¹, though some agreement exists in the IAV. The mean difference cannot be explained by the influence of river fluxes alone, as the river fluxes in the Northern Hemisphere would be less than 0.45 GtC yr⁻¹, particularly when taking into account for the anthropogenic contribution to river fluxes.

3.2 Global carbon budget for year 2013 and emissions projection for 2014

3.2.1 CO₂ emissions

Global CO₂ emissions from fossil fuel combustion and cement production reached 9.9 ± 0.5 GtC in 2013 (Fig. 5), 2.3% (including leap year correction) higher than the emissions in 2012. This compares to our projection of 2.1% yr⁻¹ made last year (Le Quéré et al., 2014), based on an estimated GDP growth of 2.9% yr⁻¹ and improvement in I_{FF} of -0.8% yr⁻¹ (Table 9). The latest estimate of GDP growth for 2013 was 3.3% yr⁻¹ (IMF, 2014) and hence I_{FF} improved -1.0% yr⁻¹, very close to our projection. The 2013 emissions were distributed among coal (43%), oil (33%), gas (18%), cement (5.5%) and gas flaring (0.6%). The first four categories increased by 3.0, 1.4, 1.4 and 4.7% respectively over the previous year (including leap year adjustment). Due to lack of data gas flaring in 2012 and 2013 are assumed equal to 2011.

Using Eq. (6), we estimate that global fossil fuel CO₂ emissions in 2014 will reach 10.1 ± 0.5 GtC (37.0 ± 1.9 GtCO₂), or 2.5% above 2013 levels (likely range of 1.3–3.5%; see Friedlingstein et al., 2014), and that emissions in 2014 will be 65% above emissions in 1990. The expected value is computed using the world GDP projection of 3.3% made by the IMF (2014) and a growth rate for I_{FF} of -0.7% yr⁻¹ which is the

Interactive Discussion

average from the previous 10 years. The I_{FF} is based on GDP in constant PPP (purchasing power parity) from the IEA (2013) up to 2011 (IEA/OECD, 2013) and extended using the IMF growth rates of 2.9 % in 2012 and 3.3 % in 2013. The uncertainty range is based on an uncertainty of 0.3 % for GDP growth (the range in IMF estimates of 2014 GDP growth published in January, April, and July 2014 was 3.7, 3.6, and 3.4 %, respectively) and the range in I_{FF} due to short-term trends of $-0.7\% \text{ yr}^{-1}$ (2009–2013) and medium term trends of $-1.0\% \text{ yr}^{-1}$ (1994–2013). The combined uncertainty range is therefore 1.2 % (2.5–0.3–1.0; low GDP growth, large I_{FF} improvements) and 2.1 % (2.5 + 0.3–0.7; high GDP growth, small I_{FF} improvements). Projections made in the previous global carbon budgets compared well to the actual CO_2 emissions for that year (Table 9 and Fig. 9) and were useful to capture the current state of the fossil fuel emissions (see also Peters et al., 2013).

In 2013, global CO_2 emissions were dominated by emissions from China (28 %), the USA (14 %), the EU (28 member states; 10 %), and India (7 %) compared to the global total including bunker fuels. These four regions account for 58 % of global emissions. Growth rates for these countries from 2012 to 2013 were 4.2 % (China), 2.9 % (USA), -1.8% (EU28), and 5.1 % (India). The countries contributing most to the 2013 change in emissions were China (58 % of the increase), USA (20 % of the increase), India (17 % of the increase), and EU28 (11 % of the decrease). The per-capita CO_2 emissions in 2013 were $1.4 \text{ tC person}^{-1} \text{ yr}^{-1}$ for the globe, and were 4.5 (USA), 2.0 (China), 1.9 (EU28) and 0.5 (India) $\text{tC person}^{-1} \text{ yr}^{-1}$ (Fig. 5e).

Territorial emissions in Annex B countries have remained stable from 1990–2012, while consumption emissions grew at $0.5\% \text{ yr}^{-1}$ (Fig. 5c). In non-Annex B countries, territorial emissions, have grown at $4.4\% \text{ yr}^{-1}$, while consumption emissions have grown at $4.1\% \text{ yr}^{-1}$. In 1990, 62 % of global territorial emissions were emitted in Annex B countries (34 % in non-Annex B, and 4 % in bunker fuels used for international shipping and aviation), while in 2012 this had reduced to 37 % (58 % in non-Annex B, and 6 % in bunkers). In terms of consumption emissions this split was 63 % in 1990 and 43 % in 2012 (33 to 51 % in non-Annex B). The difference between territorial and

[Title Page](#)[Abstract](#)[Instruments](#)[Data Provenance & Structure](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

consumption emissions (the net emission transfer via international trade) from non-Annex B to Annex B countries has increased from 0.05 GtC yr^{-1} in 1990 to 0.46 GtC in 2012 (Fig. 5), with an average annual growth rate of $11 \% \text{ yr}^{-1}$. The increase in net emission transfers of 0.41 GtC from 1990–2012 compares with the emission reduction of 0.27 GtC in Annex B countries. These results clearly show a growing net emission transfer via international trade from non-Annex B to Annex B countries. In 2012, the biggest emitters from a consumption perspective were China (23 % of the global total), USA (16 %), EU28 (13 %), and India (6 %).

Based on DGVMs only, the global CO_2 emissions from land-use change activities are estimated as $0.9 \pm 0.6 \text{ GtC}$ in 2013, slightly below the 2004–2013 average of $1.0 \pm 0.7 \text{ GtC yr}^{-1}$. However, although the decadal mean generally agreed, the estimated annual variability was not consistent between the LUC-emissions estimated based on the combined bookkeeping method and fire-based estimate and the DGVMs, except that they are small relative to the variability from the residual land sink (Fig. 6a). This could be partly due to the design of the DGVM experiments, which use flux differences between simulations with and without land-cover change, and thus may overestimate variability e.g. due to fires in forest regions where the contemporary forest cover is smaller than pre-industrial cover used in the without land cover change runs. The extrapolated land cover input data for 2010–2013 may also explain part of the discrepancy, though it would not account for the larger variability in the DGVMs.

3.2.2 Partitioning

The atmospheric CO_2 growth rate was $5.4 \pm 0.2 \text{ GtC}$ in 2013 ($2.53 \pm 0.09 \text{ ppm}$; Fig. 4; Dlugokencky and Tans, 2014). This is significantly above the 2004–2013 average of $4.3 \pm 0.1 \text{ GtC yr}^{-1}$, though the interannual variability in atmospheric growth rate is large.

The ocean CO_2 sink was $2.9 \pm 0.5 \text{ GtC yr}^{-1}$ in 2013, an increase of 0.1 GtC yr^{-1} over 2012 according to ocean models. Five of the seven ocean models produce an increase in the ocean CO_2 sink in 2013 compared to 2012. However the two data products available over that period produce a decrease of -0.1 GtC yr^{-1} . All estimates suggest

Interactive Discussion

relatively small change in the ocean CO₂ sink, consistent with El Niño neutral conditions observed in 2013. All estimates suggest an ocean CO₂ sink for 2013 that is larger than the 2004–2013 average of 2.6 ± 0.5 GtC yr⁻¹. The terrestrial CO₂ sink calculated as the residual from the carbon budget was 2.5 ± 0.9 GtC in 2013, just below the 2.7 ± 0.9 GtC in 2012 and the 2004–2013 average of 2.9 ± 0.8 GtC yr⁻¹ (Fig. 4), and also consistent with El Niño neutral conditions. The DGVMs model mean suggests the same terrestrial CO₂ sink in 2013 of 2.4 ± 1.2 GtC (Table 7), but results cover a range among models.

Cumulative emissions for 1870–2013 were 390 ± 20 GtC for E_{FF} , and 145 ± 50 GtC for E_{LUC} based on the bookkeeping method of Houghton et al. (2012) for 1870–1996 and a combination with fire-based emissions for 1997–2013 as described in Sect. 2.2 (Table 10). The cumulative emissions are rounded to the nearest 5 GtC. The total cumulative emissions for 1870–2013 are 535 ± 55 GtC. These emissions were partitioned among the atmosphere (225 ± 5 GtC based on atmospheric measurements in ice cores of 288 ppm (Sect. 2.3.1; Joos and Spahni, 2008) and recent direct measurements of 395.31 ppm, Dlugokencky and Tans, 2014), ocean (150 ± 20 GtC using Khatiwala et al. (2013) prior to 1959 and Table 8 otherwise), and the land (155 ± 60 GtC by the difference).

Cumulative emissions for the early period 1750–1869 were 3 GtC for E_{FF} , and about 45 GtC for E_{LUC} (rounded to nearest 5) of which 10 GtC were emitted in the period 1850–1870 (Houghton et al., 2012) and 30 GtC were emitted in the period 1750–1850 based on the average of four publications (22 GtC by Pongratz et al. (2009); 15 GtC by van Minnen et al. (2009); 64 GtC by Shevliakova et al. (2009) and 24 GtC by Zaehle et al., 2011). The growth in atmospheric CO₂ during that time was about 25 GtC, and the ocean uptake about 20 GtC, implying a land uptake of 5 GtC. These numbers have large relative uncertainties but balance within the limits of our understanding.

Cumulative emissions for 1750–2013 based on the sum of the two periods above were 395 ± 20 GtC for E_{FF} , and 185 ± 65 GtC for E_{LUC} , for a total of 580 ± 70 GtC,

partitioned among the atmosphere (250 ± 5 GtC), ocean (170 ± 20 GtC), and the land (160 ± 70 GtC).

Cumulative emissions through to year 2014 can be estimated based on the 2014 projections of E_{FF} (Sect. 3.2), the largest contributor, and assuming a constant E_{LUC} of 0.9 GtC. For 1870–2014, these are 545 ± 55 GtC (2000 ± 200 GtCO₂) for total emissions, with about 75 % contribution from E_{FF} (400 ± 20 GtC) and about 25 % contribution from E_{LUC} (145 ± 50 GtC). Cumulative emissions since year 1870 are higher than the emissions of 515 [445 to 585] GtC reported in the IPCC (Stocker et al., 2013b) because they include an additional 32 GtC from emissions in 2012–2014 (mostly from E_{FF}). The uncertainty presented here ($\pm 1\sigma$) is smaller than the range of 90 % used by IPCC, but both estimates overlap within their uncertainty ranges.

4 Discussion

Each year when the global carbon budget is published, each component for all previous years is updated to take into account corrections that are due to further scrutiny and verification of the underlying data in the primary input data sets. The updates have generally been relatively small and focused on the most recent years, except for LUC, where they are more significant but still generally within the provided uncertainty range (Fig. 9). The difficulty in accessing land cover change data to estimate E_{LUC} is the key problem to providing continuous records of emissions in this sector. Revisions in E_{LUC} for the 2008/2009 budget were the result of the release of FAO 2010, which contained a major update to forest cover change for the period 2000–2005 and provided the data for the following 5 years to 2010 (Fig. 9b). The differences this year could be attributable to both the different data and the different methods. Updates were highest at 0.34 GtC yr⁻¹ for the atmospheric growth rate, 0.19 GtC yr⁻¹ for the fossil fuel and cement emissions, and 0.1 GtC yr⁻¹ for the ocean CO₂ sink, all within the reported uncertainty. The update for the residual land CO₂ sink was also large (Fig. 9e), with

Title Page

Abstract

Printer-friendly Version

Interactive Discussion

a maximum value of 0.71 GtC yr^{-1} , directly reflecting revisions in other terms of the budget, but still within the reported uncertainty.

Our capacity to separate the carbon budget components can be evaluated by comparing the land CO_2 sink estimated through three approaches: (1) the budget residual (S_{LAND}), which includes errors and biases from all components, (2) the land CO_2 sink estimate by the DGVM ensemble, which are based on our understanding of processes of how the land responds to increasing CO_2 , climate change and variability, and (3) the inverse model estimates which formally merge observational constraints with process-based models to close the global budget. These estimates are generally close (Fig. 6), both for the mean and for the interannual variability. The DGVM mean correlates with the budget residual with $r = 0.71$ (Sect. 2.5.2; Fig. 6). The DGVMs produce a decadal mean and standard deviation across eight models of $2.6 \pm 0.9 \text{ GtC yr}^{-1}$ for the period 2000–2009, nearly the same as the estimate produced with the budget residual (Table 7). *New insights from the comparison with the atmospheric inversions and their regional breakdown already provide a semi-independent way to validate the results.* It shows a first-order consistency but a lot of discrepancies, particularly for the allocation of the mean land sink between the tropics and the Northern Hemisphere. Understanding these discrepancies and further analysis of regional carbon budgets would provide additional information to quantify and improve our estimates, as has been undertaken by the REgional Carbon Cycle Assessment and Processes (Canadell et al., 2013).

Annual estimates of each component of the global carbon budgets have their limitations, some of which could be improved with better data and/or better understanding of carbon dynamics. The primary limitations involve resolving fluxes on annual time scales and providing updated estimates for recent years for which data-based estimates are not yet available or only beginning to emerge. Of the various terms in the global budget, only the fossil fuel burning and atmospheric growth rate terms are based primarily on empirical inputs supporting annual estimates in this carbon budget. The data on fossil fuel consumption and cement production are based on survey data in all countries. The other terms can be provided on an annual basis only through the use

[Title Page](#)[Abstract](#)[Instruments](#)[Data Provenance & Structure](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

of models. While these models represent the current state of the art, they provide only estimates of actual changes. For example, the decadal trends in global ocean uptake and the interannual variations associated with El Niño/La Niña (ENSO) are not directly constrained by observations, although many of the processes controlling these trends are sufficiently well known that the model-based trends still have value as benchmarks for further validation. Data-based products for the ocean CO₂ sink provide new ways to evaluate the model results, and could be used directly as data become more rapidly available and methods for creating such products improve. Estimates of land-use emissions and their year-to-year variability have even larger uncertainty, and much of the underlying data are not available as an annual update. Efforts are underway to work with annually available satellite area change data or FAO reported data in combination with fire data and modelling to provide annual updates for future budgets. The best resolved changes are in atmospheric growth (G_{ATM}), fossil fuel emissions (E_{FF}), and by difference, the change in the sum of the remaining terms ($S_{OCEAN} + S_{LAND} - E_{LUC}$). The variations from year-to-year in these remaining terms are largely model-based at this time. Further efforts to increase the availability and use of annual data for estimating the remaining terms with annual to decadal resolution are especially needed.

Our approach also depends on the reliability of the energy and land-cover change statistics provided at the country level, and are thus potentially subject to biases. Thus it is critical to develop multiple ways to estimate the carbon balance at the global and regional level, including estimates from the inversion of atmospheric CO₂ concentration used here for the first time, the use of other oceanic and atmospheric tracers, and the compilation of emissions using alternative statistics (e.g. sectors). It is also important to challenge the consistency of information across observational streams, for example to contrast the coherence of temperature trends with those of CO₂ sink trends. Multiple approaches ranging from global to regional scale would greatly help increase confidence and reduce uncertainty in CO₂ emissions and their fate.

5 Conclusions

The estimation of global CO₂ emissions and sinks is a major effort by the carbon cycle research community that requires a combination of measurements and compilation of statistical estimates and results from models. The delivery of an annual carbon budget serves two purposes. First, there is a large demand for up-to-date information on the state of the anthropogenic perturbation of the climate system and its underpinning causes. A broad stakeholder community relies on the datasets associated with the annual carbon budget including scientists, policy makers, businesses, journalists, and the broader society increasingly engaged in adapting to and mitigating human-driven climate change. Second, over the last decade we have seen unprecedented changes in the human and biophysical environments (e.g. increase in the growth of fossil fuel emissions, ocean temperatures, and strength of the land sink), which call for more frequent assessments of the state of the Planet, and by implications a better understanding of the future evolution of the carbon cycle, and the requirements for climate change mitigation and adaptation. Both the ocean and the land surface presently remove a large fraction of anthropogenic emissions. Any significant change in the function of carbon sinks is of great importance to climate policymaking, as they affect the excess carbon dioxide remaining in the atmosphere and therefore the compatible emissions for any climate stabilization target. Better constraints of carbon cycle models against contemporary datasets raises the capacity for the models to become more accurate at future projections.

This all requires more frequent, robust, and transparent datasets and methods that can be scrutinized and replicated. After nine annual releases from the GCP, the effort is growing and the traceability of the methods has become increasingly complex. Here, we have documented in detail the datasets and methods used to compile the annual updates of the global carbon budget, explained the rationale for the choices made, the limitations of the information, and finally highlighted need for additional information where gaps exist.

This paper via “living data” will help to keep track of new budget updates. The evolution over time of the carbon budget is now a key indicator of the anthropogenic perturbation of the climate system, and its annual delivery joins a set of other climate indicators to monitor the evolution of human-induced climate change, such as the annual updates on the global surface temperature, sea level rise, minimum Arctic sea ice extent and others.

6 Data access

The data presented here is made available in the belief that their wide dissemination will lead to greater understanding and new scientific insights of how the carbon cycle works, how humans are altering it, and how we can mitigate the resulting human-driven climate change. The free availability of these data does not constitute permission for publication of the data. For research projects, if the data are essential to the work, or if an important result or conclusion depends on the data, co-authorship may need to be considered. Full contact details and information on how to cite the data are given at the top of each page in the accompanying database, and summarised in Table 2.

The accompanying database includes an Excel file organised in the following spreadsheets (accessible with the free viewer <http://www.microsoft.com/en-us/download/details.aspx?id=10>):

1. Summary
2. The global carbon budget (1959–2013)
3. Global CO₂ emissions from fossil fuel combustion and cement production by fuel type, and the per-capita emissions (1959–2013)
4. Territorial (e.g. as reported to the UN Framework Convention on Climate Change) country CO₂ emissions from fossil fuel combustion and cement production (1959–2013)

**Table 2.** How to cite the individual components of the global carbon budget presented here.

Component	Primary reference
Territorial fossil fuel and cement emissions (E_{FF}) global, by fuel type, and by country	Boden et al. (2013; CDIAC: cdiac.ornl.gov/trends/emis/meth_reg.html)
Consumption-based fossil fuel and cement emissions (E_{FF}) by country (consumption)	Peters et al. (2011b) updated as described in Le Quéré et al. (this paper)
Land-use change emissions (E_{LUC})	Houghton et al. (2012) combined with Giglio et al. (2013)
Atmospheric CO ₂ growth rate	Dlugokencky and Tans (2014; NOAA/ESRL: www.esrl.noaa.gov/gmd/ccgg/trends/)
Ocean and land CO ₂ sinks (S_{OCEAN} and S_{LAND})	Le Quéré et al. (this paper) for S_{OCEAN} and S_{LAND} and references in Table 6 for individual models.

Table 3. Main methodological changes in the global carbon budget since first publication. Unless specified below, the methodology was identical to that described in the current paper. Furthermore, methodological changes introduced in one year are kept for the following years unless noted. Empty cells mean there were no methodological changes introduced that year.

Publication Year ^a	Fossil Fuel Emissions			LUC Emissions	Reservoirs			Uncertainty & other changes
	Global	Country (Territorial)	Country (Consumption)		Atmosphere	Ocean	Land	
2006 Raupach et al. (2007) 2007 Canadell et al. (2007)		split in regions		E_{LUC} based on FAC-FRA 2005; constant E_{LUC} for 2006	1959–1979 data from Mauna Loa; data after 1980 from global average	Based on 1 ocean model tuned to re-produced observed 1990s sink		$\pm 1\sigma$ provided for all components
2008 (online)				Constant E_{LUC} for 2007				
2009 Le Quéré et al. (2009)		Split between Annex B and non-Annex B	Results from an independent study discussed	Fire-based emission anomalies used for 2006–2008		Based on four ocean models normalised to observations with constant delta	First use of five DGVMs to compare with budget residual	
2010 Friedlingstein et al. (2010)	Projection for current year based on GDP	Emissions for top emitters		E_{LUC} updated with FAC-FRA 2010				
2011 Peters et al. (2012b)			Split between Annex B and non-Annex B					
2012 Le Quéré et al. (2013) Peters et al. (2013)		129 countries from 1959	129 countries and regions from 1990–2010 based on GTAP8.0	E_{LUC} for 1997–2011 includes interannual anomalies from fire-based emissions	All years from global average	Based on 5 ocean models normalised to observations with ratio	Nine DGVMs available for S_{LAND} ; First use of four models to compare with E_{LUC}	
2013 Le Quéré et al. (2014)		250 countries ^b	134 countries and regions 1990–2011 based on GTAP8.1	E_{LUC} for 2012 estimated from 2001–2010 average		Based on 6 models compared with 2 data-products to year 2011	Coordinated DGVM experiments for S_{LAND} and E_{LUC}	confidence levels; cumulative emissions; budget from 1750
2014 (this study)	Three years of BP data	Three years of BP data	Extended to 2012 with updated GDP data	E_{LUC} for 1997–2013 includes interannual anomalies from fire-based emissions		Based on 7 models compared with 3 data-products to year 2013	Based on 9 models	Inclusion of breakdown of the sinks in three latitude band and comparison with 3 atmospheric inversions

^a The naming convention of the budgets has changed. Up to and including 2010, the budget year (Carbon Budget 2010) represented the latest year of the data. From 2012, the budget year (Carbon Budget 2012) refers to the initial publication year.

^b The CDIAC database has about 250 countries, but we show data for about 216 countries since we aggregate and disaggregate some countries to be consistent with current country definitions (see Sect. 2.1.1 for more details).

Table 4. Data sources used to compute each component of the global carbon budget.

Component Process	Data source	Data reference	
E_{FF}	Fossil fuel combustion and gas flaring	UN Statistics Division to 2010 BP for 2011–2013	UN (2013a, b) [UN, 2012 #68;UN, 2012 #69] BP (2014)
	Cement production	US Geological Survey	van Oss (2013) US Geological Survey (2012)
E_{LUC}	Land cover change (deforestation, afforestation, and forest regrowth)	Forest Resource Assessment (FRA) of the Food and Agriculture Organisation (FAO)	FAO (2010)
	Wood harvest	FAO Statistics Division	FAOSTAT (2010)
	Shifting agriculture	FAO FRA and Statistics Division	FAO (2010) FAOSTAT (2010)
	Interannual variability from peat fires and climate – land management interactions (1997–2013)	Global Fire Emissions Database (GFED4)	Giglio et al. (2013)
G_{ATM}	Change in atmospheric CO ₂ concentration	1959–1980: CO ₂ Program at Scripps Institution of Oceanography and other research groups	Keeling et al. (1976)
		1980–2013: US National Oceanic and Atmospheric Administration Earth System Research Laboratory	Dlugokencky and Tans (2014) Ballantyne et al. (2012)
S_{OCEAN}	Uptake of anthropogenic CO ₂	1990–1999 average: indirect estimates based on CFCs, atmospheric O ₂ , and other tracer observations	Manning and Keeling (2006) McNeil et al. (2003) Mikaloff Fletcher et al. (2006) as assessed by the IPCC Denman et al. (2007)
	Impact of increasing atmospheric CO ₂ , and climate change and variability	Ocean models	Table 6
S_{LAND}	Response of land vegetation to: Increasing atmospheric CO ₂ concentration Climate change and variability Other environmental changes	Budget residual

Model/Data name	Reference	Change from Le Quéré et al. (2013)
Dynamic Global Vegetation Models		
CABLE2.0	Zhang et al. (2013)	Updated model from CABLE1.4 (Wang et al., 2011) to include full carbon, nitrogen and phosphorous cycle (Wang et al., 2010) and land cover and land cover change.
CLM4.5BGC ^a	Oleson et al. (2013)	Updated model from CLM4.0CN to CLM4.5BGC. Major changes include: revised photosynthesis, slower turnover times for decomposition of litter and SOM, vertically resolved soil biogeochemistry, revised soil denitrification and nitrification, new fire model, and revised frozen-soil hydrology. As shown in Koven et al. (2013), these changes collectively bring model into better agreement with 20th-century C budget.
ISAM	Jain et al. (2013) ^b	not applicable
JULES ^c	Clarke et al. (2011) ^d	Updated model from JULESv1 (Cox et al., 2000) to JULESv3.2 as configured in the latest generation ESM-HadGEM2-ES (Collins et al., 2011). Higher resolution (1.875 × 1.25) and with an improved snow scheme, multi-pool soil carbon model, updated representation of land use change.
LPJ-GUESS	Smith et al. (2001)	not applicable
LPJ ^e	Sitch et al. (2003)	Decreased LPJ wood harvest efficiency so that 50 % of biomass was removed off-site compared to 85 % used in the 2012 budget. Residue management of managed grasslands increased so that 100 % of harvested grass enters litter pool.
LPX	Stocker et al. (2013a)	Addition of C-N cycle coupling.
ORCHIDEE	Krinner et al. (2005)	Revised parameters values for photosynthetic capacity for boreal forests (following assimilation of FLUXNET data), updated parameters values for stem allocation, maintenance respiration and biomass export for tropical forests (based on literature) and, CO ₂ down-regulation process added to photosynthesis.
VEGAS	Zeng et al. (2005) ^f	Improved wetland and permafrost parameterizations, high latitude temperature dependence
VISIT	Kato et al. (2013) ^g	Wood harvest flux is added to E_{LUC} , and the Loss of additional sink capacity is also included in the E_{LUC} due to the methodological change of using coordinated DGVM experiments.

^a Community Land Model 4.5;^b see also El-Masri et al. (2013);^c Joint UK Land Environment Simulator;^d see also Best et al. (2011);^e Lund-Potsdam-Jena;^f only used for total land ($E_{LUC} + S_{LAND}$) flux calculation of multi-model mean;^g see also Ito and Inatomi (2012);^h with no nutrient restoring below the mixed layer depth;ⁱ with updates to the physical model as described in Tjiputra et al. (2013);^j Further information (e.g., physical evaluation) for CNRM model can be found in Danabasoglu et al. (2014);^k using winds from Atlas et al. (2011);^l updated version "s81_v3.6gcp";^m The MACCv13.1 CO₂ inversion system, initially described by Chevallier et al. (2005), relies on the global tracer transport model LMDZ (Hourdin et al., 2006; see also Supplement Peylin et al., 2013).

Table 7. Comparison of results from the bookkeeping method and budget residuals with results from the DGVMs and inverse estimates for the periods 1960–1969, 1970–1979, 1980–1989, 1990–1999, 2000–2009, last decade and last year available. All values are in GtC yr^{-1} . The DGVM uncertainties represents $\pm 1\sigma$ of results from the nine individual models, for the inverse models all three results are given where available.

	mean (GtC yr^{-1})						
	1960-1969	1970-1979	1980-1989	1990-1999	2000-2009	2004-2013	2013
	Land-use change emissions (E_{LUC})						
Bookkeeping method	1.5 ± 0.5	1.3 ± 0.5	1.4 ± 0.5	1.6 ± 0.5	1.0 ± 0.5	0.9 ± 0.5	0.9 ± 0.5
DGVMs	1.3 ± 0.5	1.2 ± 0.6	1.3 ± 0.6	1.8 ± 0.9	1.1 ± 0.7	1.0 ± 0.7	0.9 ± 0.6
	Residual terrestrial sink (S_{LAND})						
Budget residual	1.8 ± 0.7	1.8 ± 0.8	1.6 ± 0.8	2.7 ± 0.7	2.4 ± 0.8	2.9 ± 0.8	2.5 ± 0.9
DGVMs	1.1 ± 0.7	2.0 ± 0.8	1.6 ± 1.0	2.1 ± 0.9	2.4 ± 0.9	2.5 ± 1.0	2.4 ± 1.2
	Total land fluxes ($E_{\text{LUC}} + S_{\text{LAND}}$)						
Budget ($E_{\text{FF}} - G_{\text{ATM}} - S_{\text{OCEAN}}$)	0.2 ± 0.5	0.4 ± 0.6	0.2 ± 0.6	1.1 ± 0.6	1.5 ± 0.6	2.0 ± 0.7	1.6 ± 0.7
DGVMs	-0.3 ± 0.8	0.7 ± 0.8	0.1 ± 0.7	0.1 ± 1.0	1.2 ± 0.9	1.4 ± 1.0	1.5 ± 1.2
Inversions (P/R/C)	-/-/-	-/-/-	$-0.2^*/0.7^*$	$-1.1^*/1.7^*$	$-1.5^*/2.4^*$	$1.7^*/1.9^*/3.1^*$	$1.3^*/2.2^*/2.7^*$

* Estimate are not corrected for the influence of river fluxes, which would reduce the fluxes by 0.45 GtC yr^{-1} when neglecting the anthropogenic influence on land (Sect. 7.2.2).

Global Carbon Budget 2014

C. Le Quéré et al.

Table 8. Decadal mean in the five components of the anthropogenic CO₂ budget for the periods 1960–1969, 1970–1979, 1980–1989, 1990–1999, 2000–2009, last decade and last year available. All values are in GtC yr⁻¹. All uncertainties are reported as ±1σ.

	mean (GtC yr ⁻¹)						
	1960–1969	1970–1979	1980–1989	1990–1999	2000–2009	2004–2013	2013
Emissions							
Fossil fuel combustion and cement production (E_{FF})	3.1 ± 0.2	4.7 ± 0.2	5.5 ± 0.3	6.4 ± 0.3	7.8 ± 0.4	8.9 ± 0.4	9.9 ± 0.5
Land-Use Change emissions (E_{LUC})	1.5 ± 0.5	1.3 ± 0.5	1.4 ± 0.5	1.6 ± 0.5	1.0 ± 0.5	0.9 ± 0.5	0.9 ± 0.5
Partitioning							
Atmospheric growth rate (G_{ATM})	1.7 ± 0.1	2.8 ± 0.1	3.4 ± 0.1	3.1 ± 0.1	4.0 ± 0.1	4.3 ± 0.1	5.4 ± 0.2
Ocean sink (S_{OCEAN})*	1.1 ± 0.5	1.5 ± 0.5	1.9 ± 0.5	2.2 ± 0.5	2.4 ± 0.5	2.6 ± 0.5	2.9 ± 0.5
Residual terrestrial sink (S_{LAND})	1.8 ± 0.7	1.8 ± 0.8	1.6 ± 0.8	2.7 ± 0.8	2.4 ± 0.8	2.9 ± 0.8	2.5 ± 0.9

* The uncertainty in S_{OCEAN} for the 1990s is directly based on observations, while that for other decades combines the uncertainty from observations with the model spread (Sect. 2.4.3).

Table 9. Actual CO₂ emissions from fossil fuel combustion and cement production (E_{FF}) compared to projections made the previous year based on world GDP (IMF October 2013) and the fossil fuel intensity of GDP (I_{FF}) based on subtracting the CO₂ and GDP growth rates. The “Actual” values are the latest estimate available and the “Projected” value for 2013 refers to those presented in this paper. A correction for leap years is applied (Sect. 2.1.3).

	2009 ^a		2010 ^b		2011 ^c		2012 ^d		2013 ^e		2014 ^f
	Projected	Actual	Projected	Actual	Projected	Actual	Projected	Actual	Projected	Actual	Projected
E_{FF}	-2.8%	-0.5%	>3%	4.9%	3.1 ± 1.5%	3.2%	2.6%	2.2%	2.1	2.3%	2.5%
							(1.9–3.5)		(1.1–3.1)		(1.3–3.5)
GDP	-1.1%	-0.4%	4.8%	5.2%	4.0%	3.9%	3.3%	3.2%	2.9%	3.2%	3.3%
I_{FF}	-1.7%	-0.9%	> -1.7%	-0.3%	-0.9 ± 1.5%	-0.7%	-0.7%	-1.0%	-0.8%	-0.9%	-0.7%

^a Le Quéré et al. (2009); ^b Friedlingstein et al. (2010); ^c Peters et al. (2013); ^d Le Quéré et al. (2013); ^e Le Quéré et al. (2014); ^f Friedlingstein et al. (2014).

Global Carbon
Budget 2014

C. Le Quéré et al.

Table 10. Cumulative CO₂ emissions for the periods 1750–2013, 1870–2013 and 1870–2014 in GtC. All uncertainties are reported as $\pm 1\sigma$. All values are rounded to nearest 5 GtC as in Stocker et al. (2013b), reflecting the limits of our capacity to constrain cumulative estimates. Thus some columns will not exactly balance because of rounding errors.

	1750–2013 (GtC)	1870–2013 (GtC)	1870–2014 (GtC)
Emissions			
Fossil fuel combustion and cement production (E_{FF})	395 \pm 20	390 \pm 20	400 \pm 20*
Land-Use Change emissions (E_{LUC})	185 \pm 65	145 \pm 50	145 \pm 50*
Total emissions	580 \pm 70	535 \pm 55	545 \pm 55*
Partitioning			
Atmospheric growth rate (G_{ATM})	250 \pm 5	225 \pm 5	
Ocean sink (S_{OCEAN})	170 \pm 20	150 \pm 20	
Residual terrestrial sink (S_{LAND})	160 \pm 70	155 \pm 60	

* The extension to year 2014 uses the emissions projections for 2014 of 10.1 GtC (Sect. 3.2) and assumes a constant E_{LUC} flux (Sect. 2.2).

Figure 1. Surface average atmospheric CO₂ concentration, deseasonalised (ppm). The 1980–2014 monthly data is from NOAA/ESRL (Dlugokencky and Tans, 2014). It is based on an average of direct atmospheric CO₂ measurements from multiple stations in the marine boundary layer (Masarie and Tans, 1995). The 1958–1979 monthly data is from the Scripps Institution of Oceanography, based on an average of direct atmospheric CO₂ measurements from the Mauna Loa and South Pole stations (Keeling et al., 1976). To take into account the difference of mean CO₂ between the NOAA/ESRL and the Scripps station networks used here, the Scripps surface average (from two stations) was harmonised to match the NOAA/ESRL surface average (from multiple stations) using the mean difference of -0.542 ppm, calculated here from overlapping data during 1980–2012. The mean seasonal cycle was removed from both datasets.

Interactive Discussion

Figure 2. Schematic representation of the overall perturbation of the global carbon cycle caused by anthropogenic activities, averaged globally for the decade 2004–2013. The arrows represent emission from fossil fuel burning and cement production (E_{FF}); emissions from deforestation and other land-use change (E_{LUC}); the growth of carbon in the atmosphere (G_{ATM}) and the uptake of carbon by the “sinks” in the ocean (S_{OCEAN}) and land (S_{LAND}) reservoirs. All fluxes are in units of $GtC\ yr^{-1}$, with uncertainties reported as $\pm 1\sigma$ (68 % confidence that the real value lies within the given interval) as described in the text. This Figure is an update of one prepared by the International Geosphere Biosphere Programme for the GCP, first presented in Le Quéré (2009).

Figure 3. Combined components of the global carbon budget illustrated in Fig. 1 as a function of time, for (top) emissions from fossil fuel combustion and cement production (E_{FF} ; grey) and emissions from land-use change (E_{LUC} ; brown), and their partitioning among the atmosphere (G_{ATM} ; light blue), land (S_{LAND} ; green) and oceans (S_{OCEAN} ; dark blue). All time-series are in GtC yr^{-1} . G_{ATM} and S_{OCEAN} (and by construction also S_{LAND}) prior to 1959 are based on different methods and shown as a dashed line. The primary data sources are for: fossil fuel and cement emissions from Boden et al. (2013), with uncertainty of about $\pm 5\%$ ($\pm 1\sigma$); land-use change emissions from Houghton et al. (2012) with uncertainties of about $\pm 30\%$; atmospheric growth rate prior to 1959 is from Joos and Spahni (2008) with uncertainties of about $\pm 1\text{--}1.5 \text{ GtC decade}^{-1}$ or $\pm 0.1\text{--}0.15 \text{ GtC yr}^{-1}$ (Bruno and Joos, 1997), and from Dlugokencky and Tans (2014) from 1959 with uncertainties of about $\pm 0.2 \text{ GtC yr}^{-1}$; ocean sink prior to 1959 is from Khatiwala et al. (2013) with uncertainty of about $\pm 30\%$, and from this study from 1959 with uncertainties of about $\pm 0.5 \text{ GtC yr}^{-1}$; residual land sink is obtained by difference (Eq. 8), resulting in uncertainties of about $\pm 50\%$ prior to 1959 and $\pm 0.8 \text{ GtC yr}^{-1}$ after that. See the text for more details of each component and their uncertainties.

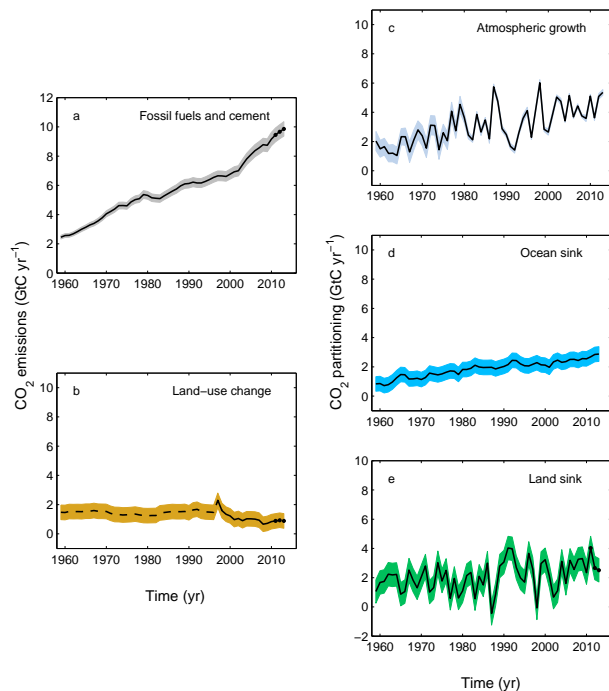

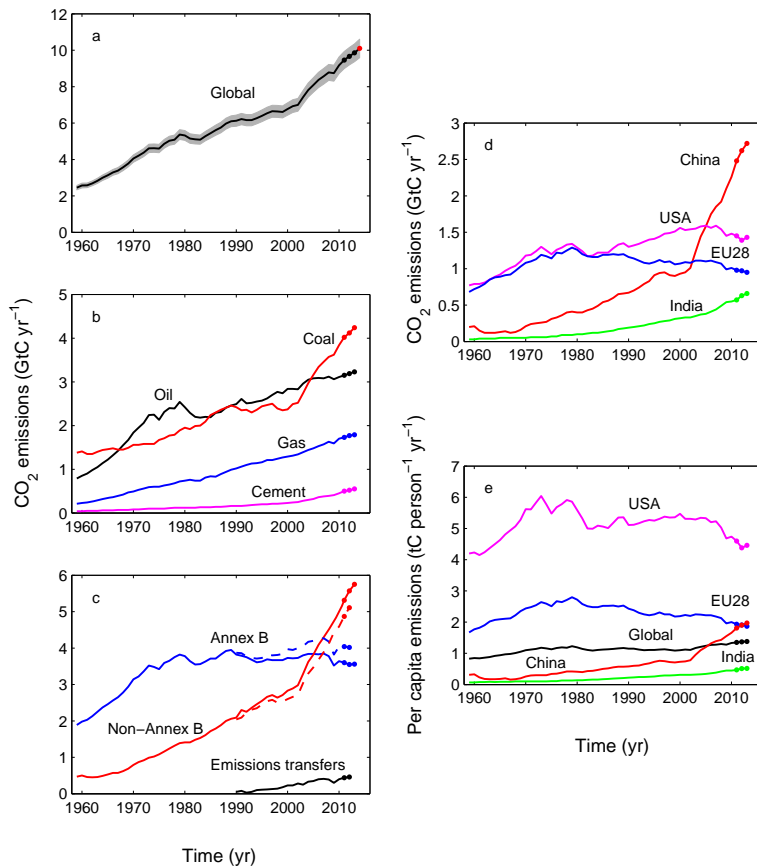

Figure 4. Components of the global carbon budget and their uncertainties as a function of time, presented individually for **(a)** emissions from fossil fuel combustion and cement production (E_{FF}), **(b)** emissions from land-use change (E_{LUC}), **(c)** atmospheric CO_2 growth rate (G_{ATM}), **(d)** the ocean CO_2 sink (S_{OCEAN} , positive indicates a flux from the atmosphere to the ocean), and **(e)** the land CO_2 sink (S_{LAND} , positive indicates a flux from the atmosphere to the land). All time-series are in GtC yr^{-1} with the uncertainty bounds representing $\pm 1\sigma$ in shaded colour. Data sources are as in Fig. 2. The black dots in **(a)**, **(b)** and **(e)** show values for 2011, 2012 and 2013, that originate from a different dataset to the remainder of the data, as explained in the text.

Figure 5. CO₂ emissions from fossil fuel combustion and cement production for **(a)** the globe, including an uncertainty of ±5% (grey shading), the emissions extrapolated using BP energy statistics (black dots) and the emissions projection for year 2014 based on GDP projection (red dot), **(b)** global emissions by fuel type, including coal (red), oil (black), gas (blue), and cement (purple), and excluding gas flaring which is small (0.6% in 2013), **(c)** territorial (full line) and consumption (dashed line) emissions for the countries listed in the Annex B of the Kyoto Protocol (blue lines; mostly advanced economies with emissions limitations) versus non-Annex B countries (red lines), also shown are the emissions transfer from non-Annex B to Annex B countries (black line) **(d)** territorial CO₂ emissions for the top three country emitters (USA – purple; China – red; India – green) and for the European Union (EU; blue for the 28 member states of the EU in 2012), and **(e)** per-capita emissions for the top three country emitters and the EU (all colours as in **d**) and the world (black). In **(b)** to **(e)**, the dots show the data that were extrapolated from BP energy statistics for 2011, 2012 and 2013. All time-series are in GtC yr⁻¹ except the per-capita emissions **(e)**, which are in tonnes of carbon per person per year (tC person⁻¹ yr⁻¹). All territorial emissions are primarily from Boden et al. (2013) as detailed in the text; consumption-based emissions are updated from Peters et al. (2011a).

Figure 6. Comparison between the CO₂ budget values estimated here (black line), and other methods and models over land regions (Table 6; coloured lines) for **(a)** CO₂ emissions from land-use change showing individual DGVM model results (green) and the multi model mean (yellow line), and fire-based results (brown), LUC data prior to 1997 (dashed black line) highlights the start of satellite data from that year **(b)** land CO₂ sink (S_{LAND}) showing individual DGVM model results (green) and multi model mean (yellow line), and **(c)** total land CO₂ fluxes (sum of **(a)** + **(b)**) from DGVM model results (green) and the multi model mean (yellow line), atmospheric inversions (MACC, v13.1 (Chevallier, 2005) in red; Rödenbeck et al. (2003) in orange; Peters et al. (2010) in purple), and the carbon balance from Eq. (1) (black). On **(c)** the inversions were corrected for the pre-industrial land sink of CO₂ from riverine input, by adding a sink of 0.45 GtC yr⁻¹ (Jacobson et al., 2007). This correction does not take into account the anthropogenic contribution to river fluxes (see Sect. 2.7.1).

Figure 7. Comparison between the CO₂ budget values estimated here (black line), and other methods and models over the ocean (Table 6; coloured lines) for individual models before normalisation (blue lines), and the three data-based products (Rödenbeck et al. (2014) in orange, Landschutzer et al. (2014) in red and Park et al. (2010) in purple). All data-based products were corrected for the pre-industrial ocean source of CO₂ from riverine input to the ocean, which is not present in the models, by adding a sink of 0.45 GtC yr⁻¹ (Jacobson et al., 2007), to make them comparable to S_{OCEAN} . This correction does not take into account the anthropogenic contribution to river fluxes (see Sect. 2.7.1).

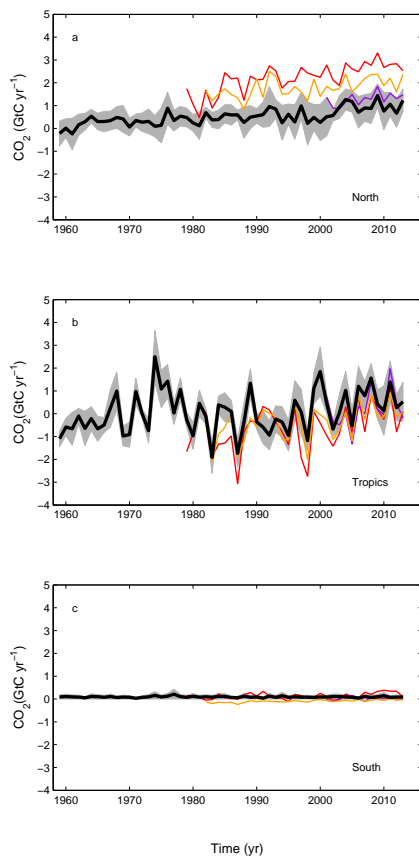

Figure 8. Surface CO₂ flux by latitude bands for the North (top panel, north of 30° N), Tropics (middle panel, 30° S–30° N), and South (south of 30° S). Estimates from the combination of the multi-model means for the land and oceans are shown (black) with $\pm 1\sigma$ of the model ensemble (in grey). Results from the three atmospheric inversions are shown (MACC, v13.1 (Chevallier, 2005) in red; Rödenbeck et al. (2003) in orange; Peters et al. (2010) in purple; Table 6).

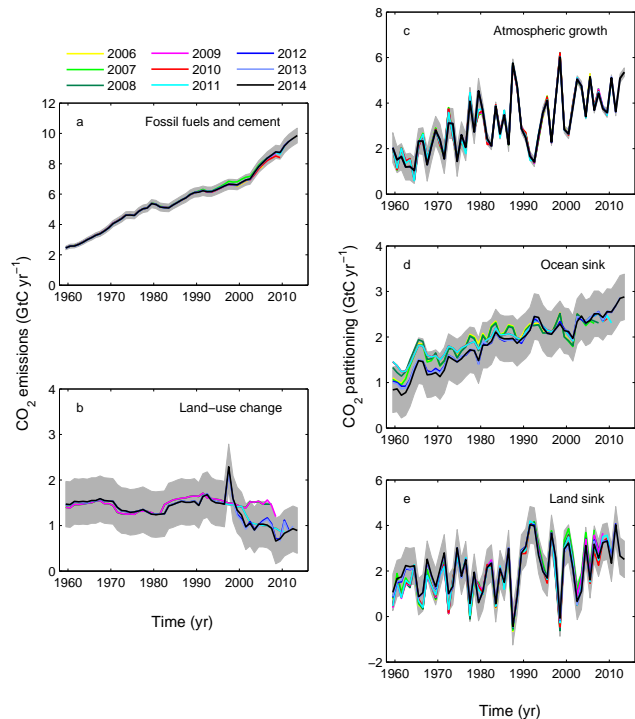

Figure 9. Comparison of global carbon budget components released annually by GCP since 2005. CO_2 emissions from both **(a)** fossil fuel combustion and cement production (E_{FF}), and **(b)** land-use change (E_{LUC}), and their partitioning among **(c)** the atmosphere (G_{ATM}), **(d)** the ocean (S_{OCEAN}), and **(e)** the land (S_{LAND}). See legend for the corresponding years, with the 2006 carbon budget from Raupach et al. (2007); 2007 from Canadell et al. (2007); to 2008 published online only; 2009 from Le Quéré et al. (2009); 2010 from Friedlingstein et al. (2010); 2011 from Peters et al. (2012b); 2012 from Le Quéré et al. (2013); 2013 from Le Quéré et al. (2014) and this year's budget (2014). The budget year generally corresponds to the year when the budget was first release. All values are in GtC yr^{-1} .
